From this point of view the germs of putrefaction cease to be mere interlopers, parasites, breeders of corruption. They come to occupy a recognized and legitimate place in the constitution of nature. Nay, not only do they fill a recognized place, but they discharge a necessary function, they play indeed a beneficent part in the drama of life. The world of lifeless matter consists—let it be put roughly and broadly—of a number of elements, carbon, oxygen, hydrogen, nitrogen, sodium, potassium, phosphorus, sulphur, &c., associated together in various ways, oxygen and hydrogen as water, oxygen and nitrogen as atmospheric air, potassium, sodium, phosphorus, in various combinations as salts of various kinds. Now these substances are just such as plants, the lower animals, and man require for their nourishment. But neither the lower animals nor man can take these inorganic substances and convert them into the living matter of their bodies. A diet of phosphate of lime, chloride of sodium, and potassium, charcoal, and so on, with a liberal allowance of air and water, though containing the same elementary substances as are found built up into muscle, nerve, and bone in a human body, is but as the sand of the desert to a hungry man. Six feet of earth may be a liberal allowance for his grave, but not for his repast. Not so with the plant. From the earth in which it is rooted, from the air to which it stretches its arms, it draws just the same elements as have been named, and builds them up into much more complex forms, into highly-organized substances. On these complex combinations of the same original elements animals and man can live. The ox crops the herbage and builds up in its own body into still higher forms the organic substances the plant yields to it; and man in turn derives nourishment from the substances the plant and the lower animal prepare for him, composed though they be of the same materials which, as beggarly elements, are practically valueless for him. And now what would happen, suppose there was ever a building up and never a breaking down? The plant, which is the first workman in nature's great manufactory, which performs the first stage in the process of converting the raw material into the finished article, the plant cannot live on boiled mutton, nor yet can it feed on the bodies of its dead companions. It is the elements it seeks. But if it is perpetually building up the elements into organic substances its own supply of nourishment will some day be exhausted, it will cease to live. If balance is to be maintained, the process by which organized bodies are broken down into elements must keep pace with the process by which elements are built up into organized bodies. Death is necessary to life. This breaking-down process the lower animals and men to some extent accomplish. A man eats bread and meat, he takes into his body complex substances, he transforms them into material for his use; they abide in his body for a longer or shorter time, give him the means of obtaining heat and energy, and are then cast out, as carbonic acid gas, water, urea, and salts—practically restored, that is to say, to their elementary form, broken down from their complex state. But animals and men die. Their bodies are masses of complex, organic substances, in that form useless for any practical part in the cycle of life. But now to sweep away this useless mass an invisible host of busy workers descends from the air, who take possession of the body, send detachments far and wide into its inmost recesses, and rest not day nor night till they have rent asunder from one another the wondrously piled molecules of

albumen, of fat, of nerve, of blood, till they have broken down the walls and torn from one another the stones of the tabernacle of flesh—till they have restored again to earth and air that which years before the plant took from them. No putrefaction without organisms; and thus life presides over the work of death.

Now, these facts that have been stated supply the foundation of the modern view of infection and contagion. The resemblance between fermentations and putrefactions and various diseases, specially those of an infectious or contagious sort, had long ago been remarked; and if the one set of occurrences was the work of organisms or germs, why not the other? Why not? In 1850 a French doctor, Davaine, on examining with the microscope a drop of blood from a patient who had died of splenic fever, observed little thread-like bodies about twice the length of a blood corpuscle. He paid little heed to his discovery. But in 1863, excited by the proof Pasteur had meanwhile offered of organisms of a similar nature being the cause of various fermentations, he made new observations, and found the same thread-like body constantly present in the blood of sheep and rabbits dead of the disease. These are the first definite observations that link contagious diseases to the life and growth of germs.

Now it so happens that about the same time ruin was threatened to one of the industries of France, that of silk culture, by the presence of a mysterious disease among the silk-worms that spread like a plague not only in France, but in Spain and Italy as well. In 1865 the loss to France by its ravages amounted to over four million pounds sterling. No measure that could be thought of seemed of the least value to stay its progress. In the distress the government of France turned to Pasteur, who had taught the French wine-growers how to prevent disease in their vines, and besought him to render his assistance. He visited the affected districts, and was speedily able to affirm that the disease was due to the presence in the insects of minute cylindrical bodies about $\frac{1}{6000}$th of an inch long, and therefore only discoverable by the microscope. These microscopic organisms had been observed years before by an Italian naturalist, Filippi; but whether they had any connection with the disease was not known. Pasteur proved they were the cause of the disease, and that it was contagious. He showed that if a silk-worm, in whose body the round bodies were present, was pounded up with water in a mortar, and the poundings painted with a brush on the leaves on which healthy worms were fed, they would all without fail be smitten with the plague. For three years he worked at silk-worm disease, and succeeded, with grievous injury to his own health, in unearthing its precise nature and in devising means for its arrest, by the adoption of which prosperity was restored to this industry. During this time, and for some years after, a hot discussion had been going on about Davaine's discovery of bacilli in splenic fever. In 1876 a young physician living near Breslau, Dr. Koch, published a paper giving a full account of the life history of the splenic-fever bacillus, and a complete demonstration that its introduction into the body of animal or man was the only cause of the disease. In the following year (1877) Pasteur, driven into the question of contagious diseases by his experiments on beer, wine, and silk-worm diseases, investigated the question, and confirmed and extended the results of Koch. Now what of splenic fever? It may attack the horse, the cow, the sheep, and man. In some years France lost by it in cattle from a half to one million pounds sterling. It is rampant, not in France only, but in Spain, Italy, Russia, and Egypt. It has appeared in this country, *transported from Russia by hair*. It is sometimes called *wool-sorters' disease*, because in this country it has been chiefly wool-sorters that have been attacked by it. The evidence is conclusive that the hides had been those of animals dead of splenic fever. Some of the blood of the animal containing the germ that is the cause of the disease, had soiled the skin and the bacillus had produced spores. These seeds had clung to the hairs, and in spite of drying had retained their vitality. In the process of sorting they had been detached and had gained entrance to the bodies of the sorters by the breath or in some other way.

It is worth stating what is the general method adopted in investigating the nature of micro-organisms. By the use of very highly magnifying powers, and by the use of staining agents, they can be seen under the microscope. In the blood of an animal dead of splenic fever an organism was discovered by means of the microscope, but no information could thus be gained as to its relationship to the disease. Often, moreover, various kinds of such living things were found, and the question arose which kind, if any, was it that produced the disease. Experimenters, therefore, attempted to grow artificially the different organisms. Some flourish and multiply in chicken-broth, others grow

well on gelatine, some on raw potatoes, while various other solids and fluids were found capable of nourishing them. Experiment showed, moreover, that a particular form of organism flourished so well in one particular fluid that, though this kind with many others were put into a flask of the fluid, the particular form took entire possession of the fluid, and no other had a chance of life against it. Here, then, was a method of sifting out one kind from another until a fluid, containing one form only, was obtained with which to experiment. Thus a drop of blood taken from an animal dead of splenic fever is placed in a flask containing meat-broth, which has been shown to be free of germs of all kinds by having stood for several days or weeks, after being boiled, without the least trace of decomposition occurring in it. The flask is plugged with wool, and is maintained at a certain heat. In a few hours the bacilli of splenic fever, present in the drop of blood, have multiplied enormously. If other kinds of organisms were present in the drop they may have grown too, but to a less extent, because the soil, so to speak, is not so suitable for them. From this flask a drop of fluid is taken and transferred to a second flask containing the same pure broth free of germs. The special bacillus multiplies here again, other forms less. From the second flask a drop is transferred to a third, and so on through six or seven flasks, till a fluid is obtained containing the one particular organism only, all the others having died out. This flask now contains what is called a **pure cultivation.** Now if the bacillus contained in this fluid is the cause of splenic fever, then the injection of a small quantity of the fluid into an animal, capable of taking the disease, ought to produce the disease in the animal. If it produces the disease, then in the blood of the animal the same bacillus should be found, and from a drop of the blood new quantities of the organism ought to be capable of being reared, by means of which, in turn, the disease can be again communicated. All these different processes must be gone through before it can be said with perfect certainty that the particular germ is the active cause of the particular disease. Besides all this, it is plain that when a cultivation of the germ is obtained, experiments may be performed to determine what substances hinder and what aid its growth, whether carbolic acid, Condy's fluid, or other agents, kill it, and so on. By such means information may be gained that would enable the disease to be arrested or stamped out.

A remarkable illustration of this may be given from Pasteur's work. He found that hens never took splenic fever, and that the disease could not in an ordinary way be communicated to them. Now a degree of heat equal to 44° Centigrade kills the splenic-fever bacillus, and the heat of hen's blood is 41° or 42°. He thought perhaps the high temperature of the fowl's blood prevented it from taking the disease. So he took a hen and placed it in a cold chamber till its bodily heat was lowered to 37°. He then injected the poison; it took the disease and died. He did the same with another fowl; but this time, at the height of the attack, he placed it in a warm chamber to raise its bodily heat up to or above the usual. It recovered. But, again, Pasteur found that an animal, that had recovered from one attack of splenic fever, was safe from a second attack. He found that he could cultivate the splenic bacillus through hundreds of generations without its violence being the least affected, provided one cultivation followed another within an interval of hours. If, however, a cultivation of the organism were left for days or months with a due supply of pure air, its violence was remarkably diminished, and *if this weakened bacillus were injected into an animal the animal was very slightly affected for a short time, but was rendered incapable of acquiring the fatal form of the disease.*

Pasteur announced his discovery; he was offered a test and accepted. In May, 1881—probably many remember an account of the experiment in the papers—in the presence of veterinary surgeons, agriculturists, and others, a flock of 50 sheep and 10 cows were brought before him. Into the bodies of 25 sheep and 6 cows he introduced some fluid containing the weakened germ, the remaining 25 sheep and 4 cows were untouched. Three weeks later the most fatal form of the poison was injected into the bodies of all the 50 sheep and 10 cows. Two days later the 25 sheep that had not received the weakened germ were dead, and the 4 cows were very ill, while the 25 sheep and 6 cows which had received it were comfortably browsing. Since that day, up to the end of 1883, more than half a million of animals were vaccinated (so to speak) in France against splenic fever, with a consequent reduction of the death rate from that disease to $\frac{1}{10}$th of what it was among non-vaccinated animals.

Briefly, then, splenic fever has been found to be due entirely to the presence in the body of the affected animal of a particular living organism, and the result of that knowledge has

been to indicate the means for stamping out the disease.

The true nature of another disease, that of tuberculosis, has within recent years been revealed by methods of inquiry similar to those just described, pursued by the distinguished German observer, Dr. Koch. It has been stated (p. 278) that tubercle is the chief cause of consumption of the lungs and consumption of the bowels, and of some forms of inflammation of

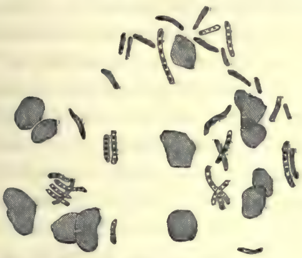

Fig. 180.—Bacilli in Spit of Consumptive Patient.

the membranes of the brain (p. 101). In the little nodules of tubercle (p. 278) Koch found a small organism, a bacillus (Fig. 180). He was able to grow it artificially, and by injecting fluid, containing his reared germs, into animals, he caused them to be affected by the disease. In the spit of consumptive patients the tubercle germ is found. The spores or seeds of the germ are not destroyed by drying, so that when the spit has become dry the seeds may be wafted about in the air, may be drawn into the lungs of a healthy person, may take root and grow and produce the disease. The popular objection, therefore, to sleep with, or be the close companion of one suffering from consumption, is not without scientific justification. On the other hand, the germ of tubercle needs a high temperature for its development, and it is not therefore likely to thrive in the outside world in temperate climates.

After the epidemic of cholera in Egypt in 1883, which spread to France, Italy, and Spain, investigations were undertaken to discover whether any special organism could be detected having any particular relationship to the disease. French, German, and British commissioners were appointed for the purpose. Dr. Koch, who was head of the German commission, detected a peculiar bacillus, shaped like a comma (,)—the comma bacillus, in the intestines of persons who had died of cholera, in the discharges from cholera patients, and also in water of which persons had drunk, who had afterwards been seized with cholera. He believed that this bacillus was the active agent in the production of the disease. Animals, however, are not susceptible to cholera, and the essential link in the chain of evidence, namely, the production of cholera in animals by the injection into their bodies of the pure cultivation of the organism, could not be obtained. In 1885 Dr. Klein, the head of the British commission, reported as the result of his investigations his inability to accept Dr. Koch's view. At present, therefore, the relation of micro-organisms to cholera is not definitely determined.

In the blood of persons suffering from relapsing fever another form of micro-organism—the spirillum (Fig. 178) has been found in great numbers, and during the intervals of freedom from fever they disappear from the blood. The fever has been produced in monkeys by injecting into their bodies blood from persons suffering from relapsing fever, and thereafter the spirilla have been found multiplying in the monkey's blood.

A micrococcus (p. 387) has been found in Erysipelas (Rose, St. Anthony's Fire), and the injection of the artificially reared organism into rabbits has produced erysipelas in them.

In the annual reports of the Registrar-General the following diseases are classed as zymotic, that is, as resembling fermentations, and apparently due to some poison operating in the blood, which poison might consist of living organisms such as have been described:—

Small-pox.	Erysipelas.
Measles.	Puerperal Fever.
Scarlatina.	Carbuncle.
Diphtheria.	Influenza.
Quinsy.	Dysentery.
Croup.	Diarrhœa.
Whooping Cough.	Simple Cholera.
Typhus.	Ague.
Enteric or Typhoid.	Remittent Fever.
Simple Continued Fever.	Rheumatism.

Now micrococci (p. 387) have been found in small-pox, scarlet fever, diphtheria, and in the diarrhœa of children, and bacilli (p. 387) have been found in dysentery and typhoid fever, although as yet no definite relationship has been proved between the organisms and these particular diseases. Inasmuch, however, as a micrococcus has been found capable of causing erysipelas, and bacilli of different kinds capable of producing splenic fever, consumption, and apparently cholera, it would appear probable that it needs only patient research, like that of Pasteur and Koch, to reveal the connection between all infectious disease and the growth of micro-organisms. How, precisely, the organism operates in the production of the disease it is

not easy to determine. It seems probable that the multiplying organism produces some chemical alterations in the blood and tissues of the animal attacked, and that the diseased conditions are the consequences of these alterations. The organism may do this by splitting up certain constituents of the blood and tissues in order to obtain what it requires for its own growth; or it may be that, in the course of its own growth and multiplication, the organism produces some special substance, a ferment, for example, and that it is owing to the operation of this special substance, manufactured by the organisms, that the symptoms of the disease are manifested.

These considerations have some very practical issues. Every infectious or contagious disease appears to be due to some form of micro-organism, one particular organism for each particular disease. The germ or organism of scarlet fever can produce only scarlet fever. It can never produce measles nor typhoid fever any more than from corn, sown in the ground, can a crop of potatoes be expected. Each organism produces its own disease and none other; and the special disease cannot arise unless its germ has gained entrance to the body. They may gain entrance in many ways. They may be present, like putrefactive germs, in the air, in food, in drink. They may be received on one's clothes; they may be harboured under one's thumb-nail; a hostess may dispense them with her hospitality; a friend may impart them by a kiss. But, though the channels by which they spread are inexhaustible, *they have one origin and one only*, and that is a preceding case of disease. Germs of measles, of diphtheria, of typhoid fever, can no more develop anew than can germs of putrefaction, which, it will be remembered, are always derived from parents like to them. If typhoid fever germs gain entrance to a person's body they came from the body of some one, whether he can be found or not, who had the fever before him. The organisms enter the body of a person and multiply there. They are cast off from his body, some by the air which be breathes out, some by his skin, some by the kidneys, some by the way of the intestinal canal. One kind of germ may be particularly abundant in the discharges, may be able to multiply in organic fluids, so that the smallest quantity of such a fluid gaining entrance to food or drink is capable of imparting the disease to those who partake. Another kind of germ, on the other hand, may be drowned, so to speak, in liquid, and may rather be propagated by spores suspended in the air. But that is a mere detail in the life history of the germ. In all cases, however, it is the introduction of the bacterium, the micrococcus, the bacillus, or whatever it be, it is its entrance into the body, by whatever channel, that sets up the disease.

This view of infectious diseases thus affords the hope and suggestion of a method of diminishing, if not of getting rid of, such diseases altogether, and to some extent also indicates the direction in which their cure is to be sought. If the particular organism of each contagious disease were known, the condition of its life and activity understood, and the circumstances hurtful to, or destructive of, its life fully ascertained, there is great probability that this knowledge would at once suggest a method by which its multiplication in the living body could be arrested, and the disease thus cured. Even without such knowledge, however, the view indicates the means for arresting the spread of contagious diseases and diminishing their occurrence. The means consist in preventing the spread of the germs from an existing case of disease. Too often, however, one case of a contagious disease is simply the breeding ground of a multitude of other cases, because no steps are taken to prevent the scattering abroad of the germs. To prevent such an occurrence methods are adopted for destroying the disease germs that have proceeded from the patient's body. These methods are stated under DISINFECTION.

Two misunderstandings must be guarded against. In the early part of this article the grounds were stated for the assertion that the organisms of putrefaction were everywhere, and could not be avoided. There can be no doubt that everyone daily swallows and draws into the lungs hundreds of them. These germs of putrefaction are powerless to harm the living human body. Moreover, by no possibility, it would appear, can such organisms be changed into forms capable of acting in a poisonous manner on the living body. To repeat, it is not the ordinary germ of putrefaction that does harm; it is a particular form of organism for each particular disease. The second point to be noticed is that disease germs may gain entrance to a person's body and yet he may not suffer from the disease. Just as in nature each plant grows best in a particular soil, and in some kinds of soil certain plants cannot grow at all, so disease germs may enter a person's body but be unable to thrive there. In other words, the person is able to resist the disease. Just as there are

soils that will grow anything, so there are persons who catch everything that is going.

Nothing gives a man so great disease-resisting power as good health. That man secures himself best against infectious as against other disease, so far as man can secure himself, who, besides keeping far from the source of the infection, lives regularly and temperately in diet and in conduct.

Epidemic and Endemic. It is the fact of contagion that gives the peculiar character to diseases called **Epidemic** diseases. One person affected with small-pox comes into a community. In a short time others catch it from him. Each one of these communicates it to others, and thus the disease spreads among the people. It becomes epidemic (Greek *epi*, upon, and *dēmos*, the people). Small-pox, measles, and scarlet fever are thus types of epidemic diseases, diseases capable of over-spreading a community in a brief period. On the other hand such diseases may appear here and there, not spreading for some reason or another, but an odd case occurring unconnected with others, so far as known. Such cases are said to be **sporadic.** In opposition to epidemic is the word **endemic.** The essence of an epidemic disease, as we have seen, is a poison, capable of multiplying in a human body, of being cast out of the body, and of being passed from person to person, communicating the disease. Now an endemic disease is not one which can be so passed and conveyed from one person to another regardless of place. It is linked with some particular district, so that a person is not liable to it unless he comes within the affected district, and perhaps by leaving the district he may get rid of it. It depends, that is to say, upon some peculiarity of climate, of water supply, or drainage of the district in question. Thus goitre (p. 210) affects persons living in certain parts of Derbyshire, in certain Swiss valleys, &c., and persons will not be affected by it if they keep away from the localities where it prevails. It is not, therefore, epidemic, but endemic.

DISINFECTION.

It has been shown that infectious diseases are communicated from a sick person to a healthy person by material thrown off from the body of the sick person, the active part of the material being probably some form of living organism. It has been seen that the poisonous material may come off from the patient's body in his breath, in discharges from the mouth and throat, from the skin, from the bowels, and from the kidneys. It is desirable that as soon as possible all poisonous material should be destroyed in one way or another to prevent the spread of the disease. All the means employed to accomplish this are included under the term disinfection, and the materials that may be used for the purpose are called disinfectants.

The **disinfectants** commonly used are carbolic acid, chloride of lime, Condy's fluid (which is a solution in water of permanganate of potash), sulphurous acid, obtained from burning sulphur, Burnet's fluid (a solution of chloride of zinc), sulphate of copper (blue vitriol) dissolved in water, and sulphate of iron (copperas), sulphuric acid (oil of vitriol), and hydrochloric acid (spirit of salt).

These substances ought to be used in such a way as to destroy the matter of contagion. There are some substances which, strictly speaking, do not destroy the contagious matter, but simply prevent its growth and multiplication. These are called **antiseptics**; and a good example is carbolic acid in weak solutions. The living matter of contagion cannot multiply when exposed to the action of an antiseptic, but if the antiseptic be removed the contagion may then go on to multiply. Its growth is merely *arrested for the time being*—the living organisms are not killed. There is another class of substances which may remove the offensive smell of decaying matter without killing or hindering the growth of contagion in it. These are **deodorants.** It is a true disinfecting action that is wanted, an action which will kill the contagion, so that neither at the moment nor at any future time can it become capable of doing harm.

The manner in which disinfectants should be employed for various purposes will now be stated.

To disinfect a patient's body. The patient should be kept perfectly clean. His body should be sponged daily with lukewarm water, to which a small quantity of ordinary vinegar (acetic acid) may be added. When scales or crusts are separating from the skin, the body should also be daily anointed with lard, or with olive-oil or glycerine, with every 40 ounces of which one ounce of pure carbolic acid should be mixed. This prevents the scales, &c., being scattered about in the air of the room, and at the same time acts as a disinfectant.

To disinfect nurses' or other attendants' hands, the best method is washing in water made pink with Condy's red fluid, or the permanganate of potash itself, or in water in

every two pints of which 1½ ounces of carbolic acid have been dissolved. *All dirt should be removed from under the nails in the process of washing.*

To disinfect clothes, they should, immediately on removal from the patient, be steeped for at least an hour in water, every gallon of which contains a quarter of a pint of carbolic acid. The acid is, however, dear; in its place water containing two ounces of chloride of lime to the gallon (1 pound to 8 gallons) may be used, and has the merit of cheapness. Care must be taken that only the clean water is used, containing no particles of the lime, which would burn the clothing. To prevent this a wooden tubful of the solution should be made at a time. The chloride of lime should be well stirred with a stick and then left to settle. After it has quite settled the clear liquid from the top can be drawn off as required. After steeping the clothes should be washed and boiled. Rags and scraps, not to be kept, should be immediately burnt. Articles of clothing that cannot be so steeped and washed, beds, &c., should be exposed to the fumes of sulphur, applied as directed for disinfecting rooms.

To disinfect discharges from the bowel, &c., they should be passed into vessels already containing a disinfecting solution. A cheap one is made by chloride of lime, one pound to the gallon of water. A stock of it should be kept, and some placed in each vessel as required. For the same purpose water, containing oil of vitriol (sulphuric acid), in the strength of one ounce of acid to a gallon of water, may be employed. A mixture used for the same purpose is made of 8 ounces of sulphate of zinc (white vitriol), 1 ounce of carbolic acid, and 3 gallons of water. On the whole, the chloride of lime is as useful as any, and very cheap. Plenty of the disinfectant should be mixed with the discharge. When the whole has been emptied into a water-closet the basin should be well flushed with water, to prevent the disinfectant collecting in the pipes and eating through them. If there is no water-closet—if, for instance, a dry closet is in use, as in the country—the discharge should be received in a vessel containing a solution of oil of vitriol or spirit of salt (of the strength of 1 ounce to 20 of water); chloride of lime should be added, and the whole thrown into a pit in the ground far from all wells or other water supply, and fresh earth thrown upon it. All chamber vessels should be washed in an acid solution, water containing one ounce of oil of vitriol, or spirit of salt, to the gallon.

To disinfect rooms, sulphur or chloride of lime should be used. Windows must be tightly closed, fireplaces and all crevices and cracks properly blocked up. Articles of clothing, bedding, &c., should be hung on lines. An iron vessel is placed in the middle of the room, containing one pound or more of sulphur, according to the size of the room (1 pound for every 1000 cubic feet of space), and, when everything is ready, the sulphur is to be lighted by placing a live coal on it. The door is then tightly closed and left so for 24 hours. Thereafter windows and doors are opened; and the room is freely ventilated for other 24 hours. After this has been done the ceiling should be whitewashed and the walls washed down. If the walls are papered, the paper should be washed off and burnt. Wood-work should be washed with water and soft soap. If chloride of lime be used it should be placed in a large shallow dish, and sulphuric acid, diluted with water, poured upon it. The rest of the procedure is the same as described. It is to be noted that the chlorine gas will remove the colour from coloured stuffs.

Heat is by far the best disinfectant. The best way of disinfecting beds, bedding, and articles of clothing that cannot be washed easily, is to expose them in a hot-air chamber for two hours or more to a heat ranging between 210 and 250° Fahrenheit.

As such an arrangement is only possible in hospitals, &c., and many other methods of disinfection are often not at hand, it should be stated that the sanitary authorities of Glasgow have found that thorough washing and boiling, in the ordinary way, are sufficient to disinfect them completely. In the absence of other methods, then, if all clothes of every description were plunged, immediately on removal from the patient, even before passing from his room, into tubs containing water and ordinary washing soda, and so carried from the patient's room, allowed to steep, and then washed and boiled, the risk of communicating disease by them would be reduced to very little.

Rules to be adopted in every case of infectious disease to prevent infection spreading:—

1. Place the patient in a room by himself, from which carpets, curtains, and hangings of every description, including pictures, &c., have been removed. All furniture, except a wooden table and chair, should also be removed. The room should be well ventilated. This is best done by keeping a fire always burning in the

grate. The floor should be kept clean, and sprinkled with Condy's fluid, or solution of carbolic acid, 1 ounce in 20 of water. The door should be kept closed, and a sheet should hang outside it, and be sprinkled daily with the Condy's fluid or carbolic acid solution.

2. Let none come near the room except the nurse and medical attendant. The nurse should wear some dress that will wash. She should keep her hands clean by washing, as noted above. When she must attend to other household duties, she should take off her dress before leaving the room and put on another kept hanging outside for the purpose. She should mix as little as possible with other members of the household.

3. All cups, plates, and utensils used by the patient should be passed through a solution of chloride of lime (2 ounces to the gallon of water) immediately on being taken from him, and should be afterwards washed in boiling water.

4. All towels, handkerchiefs, clothes, &c., used in the room should be steeped in the weak chloride of lime or carbolic acid solution.

5. All the patient's discharges, spit, vomit, discharges from bowels, &c., should be treated as noted on p. 396. All remains of food and drink should be similarly treated and thrown out.

6. The patient should be kept clean, as directed on p. 395.

7. On recovery, and before mixing with other members of the household, the patient should be bathed and clothed in a completely fresh set of clothing, from the skin outwards, which clothing must not have been kept in the sick room.

8. After the removal of the patient, the room and all articles of clothing left in it should be disinfected, as directed on p. 396.

9. The house should be kept clean and well ventilated during the sickness, the water-closets being specially attended to.

10. Should the patient have died, it is desirable to disinfect the body by wrapping it in sheets wet with carbolic acid solution (1 ounce of acid to 20 of water), or chloride of lime solution (1 ounce to 40 of water); and sawdust soaked in either of these solutions may be placed in the coffin.

If these rules seem troublesome to follow out, it should be remembered that the duty to the healthy is not less than to the sick; and where they are neglected and infection spreads, the moral guilt resting on those who have been neglectful is great.

INFECTIOUS FEVERS ATTENDED BY RASH (*Eruption*).

General characters. Fevers accompanied by eruptions (rashes) on the skin were classed by the old authority, Cullen, as **exanthemata.** This term is derived from two Greek words, *ex*, out, and *antheo*, to blossom, and means, therefore, a blossoming out. The phrase **exanthematous fevers** is largely used in medical works to include all the fevers, attended by rash, which are described under the above heading. They have several characters in common.

1. They are all due to the introduction into the body of some special material whose growth in the body is attended by the progress of the disease. They are all contagious or "catching."

2. The fever does not show itself till some time after the poison has obtained entrance into the body. There is an interval, that is to say, between the time the person becomes infected and the time he actually becomes fevered. This interval is called **the period of incubation.** Incubation means the act of hatching, and the idea is that the eggs, so to speak, of the disease require to be in the body for sometime before the disease is hatched out of them.

3. The hatching being completed, the fever appears, lasts a definite time, and runs a certain course in each case.

4. The disease is accompanied by a rash, of a special kind for each fever, which appears and lasts for a certain time, and goes through a regular series of changes.

5. Each fever ends at a certain time, in some cases suddenly after copious sweating or loose motions of the bowels, in other cases gradually diminishing till it has disappeared. In the former cases it is said to end by **crisis** (Greek *krisis*, a decision or turn); in the latter cases it ends by **lysis,** meaning a loosening (Greek *luo*, I dissolve).

6. The fever attacks the same person once only as a general rule.

Regarding these general characters some additional remarks may be made. The first—the catching nature of the eruptive fevers—is very important to notice. Some are much more catching than others. Most people are aware how difficult it is to prevent scarlet fever and measles from spreading, and, among unvaccinated people, small-pox. Typhoid fever, on the other hand, can be more easily confined if great care can be taken to disinfect the patient's discharges and to prevent them in any way getting near to any water supply. It is also important

to notice that in no other way can such a fever arise than by its seed having been sown. It cannot arise anew. It never can be caused by exposure to cold merely, by errors in diet, or in any such way. It cannot, therefore, arise from the entrance into a house of mere sewage gas, and the contamination of the air so caused. This is a point not quite understood. A house may be badly drained, or the drains may not be perfect, and gas from the sewers may thus pass into the house. This is undoubtedly a great evil, because the inmates of the house, breathing the bad air, are liable to suffer from headaches, sickness, sore throats, and various other states of ill-health. Still worse results may follow, for the persons, weakened in their general health, are thus ready victims for any disease they may come in contact with, and fall a prey to special diseases, which, in vigorous health, they would have had a great chance of resisting. But the gas from the drains, *pure and simple*, cannot produce measles, scarlet fever, diphtheria, typhoid fever, or any other special fever. It is only possible for such a fever to be communicated by drains, if the particular poison that is the cause of the fever, has been cast into the drains, from some house, where that particular fever already exists. The mere fact of a drain of a house being in a bad condition is not, therefore, sufficient evidence of the source of a special fever. Drains are only one of many channels along which contagion may spread.

The period of incubation (hatching) varies for different fevers, as shown in the table on p. 399. This is not to be forgotten in trying to trace the source of the disease. A person may move from one part of the country to another, and, some days after he has entered his new abode, fever may declare itself in his household. He must not, without deliberation, blame the new house. The disease may have been brought with him; and it may be his old place of living that is to blame.

While these fevers always have a definite course, the illness may not end with the natural conclusion of the fever. Some disease of kidneys, lungs, bowels, or other organ may arise in the course of the fever, prolonging the illness or causing death. It is to such causes, **complications** as they are called, that relapses are due. They are not, as a rule, renewed attacks of the original fever, but interruptions to the recovery owing to the affection of some organ that has specially suffered.

The facts that these special fevers have a regular progress of their own, and will end at a certain time, unless something occurs to disturb the course to recovery, afford important indications for treatment. So far as present medical knowledge extends, to attempt to cut short the fever at any stage is vain. Such a thing would only be attempted or suggested by ignorance. It could only be possible if one knew the real character of the material that caused each fever, and of something that was able to destroy it in the blood of the person ill, without also injuring the patient. Such knowledge is not possessed regarding any of the eruptive fevers (see CONTAGION, p. 384). All, therefore, that one can do for a fever patient is to aid the progress of the disease, to watch the state of the organs specially liable to give way in the particular case, and to avoid the complication if possible, and by proper dieting to maintain the patient's strength for fighting out the disease.

The general treatment of fever appears thus to be easily understood and not difficult to carry out. In fact it comes to be a matter rather of nursing than of medicine giving. To a great many people such treatment is too simple. The doctor walks in daily, carefully looks at his patient, asks a few questions, gives some instructions about food—perhaps orders a dose of simple opening medicine—and goes. Some people regard this as trifling. They are not satisfied if they have not the accustomed "bottle" to administer in frequent spoonfuls. The treatment is not heroic enough unless several mixtures of various kinds and colours accompany the progress of the fever. If the doctor does not "come up" to their expectations in this respect, they busy themselves wondering at it, discuss the matter with their friends, perhaps, and as often as not convince themselves of the necessity of making up for the doctor's omissions by administering, unknown to him, some remedy they think suitable to the case. This, or something like this, is not an uncommon experience. Now everyone in charge of a fever patient ought to remember that the sin to avoid is meddlesomeness. If the patient is kept dry and clean in bed, if small quantities of beef-tea, milk, thin mutton-broth, and similar foods are given frequently, so that within 24 hours sufficient for nourishment has been supplied, if care is taken that water is regularly passed, and the bowels are regularly moved, for which an occasional dose of castor-oil, seidlitz-powder, &c., may be necessary, and if, generally speaking, the patient is carefully and quietly tended, that is the main part of the treatment for a case of fever running an ordinary course.

TABLE OF FEVERS ATTENDED BY RASH.

Name of Fever.	Period of Incubation (Hatching).	Rash appears.	Rash fades.	
Scarlet Fever.	4 to 6 days.	2d day of fever.	5th day of fever.	Scarf-skin begins to peel by 10th day, and continues separating for 4 or 5 weeks after.
Measles.	12 to 14 days.	3d or 4th ,, ,,	7th ,, ,,	
Small-pox.	12 to 14 ,,	3d ,, ,,	Crusts of pox begin to fall about 14th day.	Rash first pimples, then blebs, then the fluid of the blebs becomes matter, and by 14th day has dried into crusts.
Chicken-pox.	13 days.	1st ,, ,,	Crusts begin to fall about 7th day.	Rash of pimples becomes blebs; scabs formed by 6th day.
Typhoid Fever (Enteric Fever).	Uncertain. In some cases 21 days.	7th or 8th ,, ,,	Comes out in crops, till end of 3d week.	Fever gradually passes away after 21 days, but is often prolonged by complications, &c.
Typhus Fever.	5 to 12 days.	5th to 7th ,, ,,	Beginning of 3d week.	Fever lasts 14 days. Crisis in 3d week.
Dandy-fever (Dengue).	5 to 6 days.	3d ,, ,,	5th or 6th day of fever.	Second attack of fever and rash follows first after two or three days, lasts shorter time.

Scarlet Fever (Plate VI.) is extremely infectious, very common among children, and often more dangerous because of its consequences than on account of the actual fever.

The **symptoms** of an ordinary case are that the person complains of shivering, weariness, headache and sickness, and *sore throat.* In children a convulsive fit, instead of shivering, not seldom begins the illness. There is great heat and dryness of the skin, and frequently the dulness and drowsiness of the patient are quite marked. Some amount of delirium is frequently present. There is thirst but no desire for food. The pulse is very fast. The appearance of the tongue is peculiar. It is thinly coated with a white fur, but is red at the edges and tip, and numerous minute red points are seen standing out, giving an appearance indicated by the phrase—"strawberry tongue," or "raspberry tongue." This is specially seen on the fourth or fifth day of the fever. The sides of the jaws are slightly swollen, stiff, and sore. On the *second* day of the fever the rash comes out. It comes out in fine red points so numerous and grouped so closely that the skin appears red all over. Appearing first on the face, sides of the neck, and breast, it is soon spread all over the body. It is most intense by the fourth day, and begins to fade on the fifth, disappearing before the end of the seventh. The intense redness of the skin may be shown by contrast, by drawing the point of the finger firmly over it. A white mark is produced, to which the redness quickly returns. The soreness of the throat may be felt a day or two before the fever—it increases up to the time of the rash appearing—the tonsils (p. 136) being very red and swollen, and in ordinary cases it diminishes when the eruption reaches its height. With the fading of the rash the pulse becomes less quick, the fever lessens, and all the symptoms improve, and in the course of a few days the fever and its attendant quick pulse, &c., has departed.

With the disappearance of the rash another peculiarity of the disease presents itself, namely, desquamation or shedding of the skin. The scarf-skin begins to separate in fine or large scales, or in large flakes. It begins on the neck and chest, spreads to the other parts of the body, and to the hands and feet last. Sometimes the scarf-skin of the hand will separate all together as a glove, or that of the foot like a slipper. It usually peels off in large pieces. This shedding of the skin lasts a considerable time. As a rule it is complete by the *sixth* week from the beginning of the fever, but it may end much sooner.

Now the chief elements in these symptoms are the sore throat, the scarlet rash, and the shedding of the skin.

While the above statement gives the symptoms and course of an ordinary fully-developed attack of scarlet fever, there are some varieties.

The attack may be mild, exhibiting the main symptoms but in a very slight degree, and often after the first day or two the patient is so little affected that he or she seriously objects to the confinement. It is to this form the term **scarlatina** is applied. It means merely a mild attack of scarlet fever. Practically, however, *the mild attacks are often found to be more serious than the severer form* just described. *Scarlatina is capable, by infection, of communicating the worst type of the disease, causing rapid death.* Moreover, the evil consequences, so common in the disease, as readily attend the mild as the

severe form. In a mild case it is often difficult to impress the patient, or, in the case of a child, its parents or nurse, with a due sense of the risks. Less care is exercised, there is improper exposure, and dropsy or other symptoms of kidney disease speedily appear. *The mildest case of scarlatina ought to be treated with the same watchful care as the most severe.* There are even milder cases of scarlet fever than those noted. A child is feverish and unwell for a day or two, and apparently becomes quite well, though unusually pale and not strong. No rash has appeared, or at least has been noticed. But, in a week or ten days after, the glands at the side of the jaws swell, the ears become sore, perhaps the skin peels, or other symptoms lead to the conclusion that the child has suffered from scarlet fever.

Again there is a malignant form of the disease, in which there are great brain disturbance, convulsions, and low muttering delirium. The tongue is dry, the throat dark-red, ulcerated, and sloughing. The rash comes out late, and speedily disappears. Death may occur before the rash has time to appear.

Scarlet fever occurring at or immediately after childbirth assumes very fatal characters. It is a form of puerperal fever.

The **results** of scarlet fever are many. Abscesses may form in the throat or in the glands at the sides of the jaw; suppuration may occur in the nostrils and in the eustachian tube (p. 356) leading to the ear. Disease of the ear, accompanied by discharge and ending in deafness, is common. Various affections of the membrane surrounding the heart (pericardium, p. 238) and lung (pleura, p. 266) may arise. Rheumatism is apt to follow. The chief result is inflammation of the kidneys (p. 295), attended by dropsy and albumen in the urine. Inflammations of the eyes are not infrequent.

The **infection** of scarlet fever is undoubtedly at its worst during the shedding of the skin, but not at this period only. It is very probable that the sore throat is also infectious, and that therefore the disease is "catching" from its commencement to its termination.

Treatment.—*Disinfection should be practised from the beginning in the manner* advised on p. 396. At the beginning of the disease nothing is more valuable than a warm bath, which the patient should remain in for from 20 minutes to half an hour. Before the bath a double-strong seidlitz-powder should be given, to children one or two tea-spoonfuls of citrate of magnesia or a dose of castor-oil. Failing the bath, the person should be wrapped, naked, in a blanket wrung out of warm water and rolled in warm dry blankets. After an hour or more the wet things may be removed and dry warm clothes put in their place. The patient should be kept strictly to bed in a well-ventilated room, in which a fire is kept burning. If the fever runs high the wet pack *with cold water* may be repeatedly used if soothing to the patient. For food, milk, beef-tea, strained mutton-broth, switched eggs, and such articles are allowed. To encourage the action of the skin and kidneys the ammonia and ether mixture (PRESCRIPTIONS — FEVER MIXTURES) is valuable. Inhaling the steam of boiling water or sipping warm milk relieves the throat. A warm application over the throat may also be used if the pain is severe. Sometimes nothing is so soothing as allowing a piece of ice to melt in the mouth, and with children giving a tea-spoonful of iced milk or water now and again. If the fever runs high, quinine is the best remedy, of which one grain for every two years of age is given, and repeated every six hours as required. For adults the dose is 5 or 10 grains. When the fever has departed, strengthening food is necessary, and iron and quinine tonics. Daily during the progress of the case, including the period of fever, sponging the body with lukewarm water containing some vinegar is very relieving. The whole body need not be done at once, but by two bathings each day. When the skin begins to separate the body should be rubbed all over with carbolic or camphorated oil. This prevents the scales of the skin being scattered through the air, and diminishes the risk of infection. This should be repeated daily till all the skin has separated. The patient should not be permitted to leave his room or mix with others till all the skin has been shed, and then only after proper disinfection, as recommended on pp. 395, 396.

Grave cases, and cases of kidney disease, &c., must be in the care of a physician. Discharge from the ear should, from the very first appearance of it, be treated as advised for that affection on p. 398.

Measles (*Morbilli—Rubeola,* Plate VI.) is an infectious disease occurring most commonly among children, not because grown-up people are less liable to be attacked, but because most people have it in childhood, and one attack protects, as a rule, against another. This is not a rule, however, that has no exceptions; for many cases have been observed of persons attacked for the second time, though that is not common.

ERUPTIVE FEVERS.

Typhus in advanced stage 13^{th} day - Spotted Typhus p 410.

Typhoid, Enteric or Gastric Fever, about 16^{th} day Rose Rash of Typhoid p 413

The **cause** of the disease is, without exception, contagion; that is to say, a special kind of poisonous material is thrown off from the body of a person suffering from measles, which, gaining entrance to the body of a healthy person, gives rise to a new case of the disease. It can never arise anew. The measles germs or seeds must be sown before a crop of measles can arise. Measles thus spreads, like scarlet fever, from person to person, one case being capable of infecting any number of others. It clings to clothing, and to other surfaces. Many people forget this. They visit those sick of the disease without fear for themselves, because they have had it before, forgetting the risk they run of carrying away with them seeds of the disease, to infect others with whom they come in contact. Parents too often forget it when they send their children out to play, or back to school, a sufficient time after their recovery, but without previously disinfecting their clothing. It is for such reasons that, when one of a family is sick of measles, the others, if they are living in the same house, should be kept at home, not only from school but from playing with neighbours' children, lest they spread the fever. It would appear that one who has suffered from measles is scarcely free of the power of imparting the disease till about the end of a month. Of course the infection may cling to rooms and clothing, that have not been disinfected, for a much longer time. Measles is infectious almost from the beginning, at least it is infectious even before the rash has appeared, and therefore, even before the real nature of the affection is quite certain. A patient may, thus, have already imparted the disease to others before it could be known that he was himself suffering from it. This is different from scarlet fever, in which the chief period of infection is while the scarf-skin is separating—the period of desquamation, as it is called.

Symptoms do not show themselves till from twelve to fourteen days after infection. The attack begins with signs resembling those of cold-in-the-head (catarrh, p. 154). There are chills or shivering fits, in children sometimes convulsions, followed by evident fever. The appetite is lost, the tongue white, and there may be vomiting. Cough is present, generally of a harsh barking character. There is sneezing, the eyes are red and watery and sensitive to light, and the head aches. These symptoms increase up to the fourth day, when the rash begins to appear, at first on the forehead and temples, at the edge of the hair, and then on the cheeks, chin, and neck. It then extends downwards over chest, arms, belly, and legs. On the fourth day the fever seems to be at its height. It may reach 104° Fahrenheit (see p.10), accompanied by rapid pulse and sometimes delirium. The rash consists of well-marked, red, roundish spots, *raised above the skin.* Appearing first here and there, they quickly form groups, which run together into irregular patches. When they are numerous the skin is swollen. The face is thus very red, and irregularly swollen and rough, when the rash is well out. The spots being raised above the surface, the skin feels very rough, and so measles is easily distinguished from scarlet fever, in which there are no raised spots but only a general redness. If the rash is well 'out' by the fourth day, then on the fifth the fever usually is much diminished, the cough is softer, and the pulse less rapid. Within two days of its appearance the rash begins to fade, disappearing from the different parts in the order in which it came, but leaving a mottling of the skin, of a dusky colour, which does not completely fade for ten days or longer. Very fine scales separate from the skin, of the face and neck in particular, on the disappearance of the rash. In ordinary cases, without complications, the fever has almost if not quite passed away by the seventh day, leaving the patient weak.

It is very common for the cough to be the first thing to attract special attention. A child, who has been restless and irritable during the day, rouses its parents in the night by a hoarse barking cough, which immediately suggests croup to their minds. It has not the metallic, brassy ring of croup, however, for which it may be mistaken till, in one or two days, out comes the measles rash, showing the true nature of the illness.

Measles is not the very simple disease that many people seem to imagine. Bronchitis is a very common complication, maintaining the high fever beyond the sixth or seventh day, delaying recovery, or causing death. In young children the attack of the disease with the accompanying affection of the chest may be so severe as to cause death before the rash has time to appear. In hot weather an attack of diarrhœa is serious, and in hot climates dysentery is not an infrequent bad attendant of the attack. In cases of children with not robust constitutions, measles is apt to leave very weakened conditions of general health. Serious inflammation and ulceration of the eyes, discharges from the ears, and swellings of glands often

follow an attack of measles in unhealthy children, and are very difficult of cure.

Persons may suffer from measles and mumps or whooping-cough at the same time.

Treatment.—From the very beginning of the disease, before the suspicion of its nature has time to be confirmed or otherwise, the patient should be separated from others, and steps should be taken for disinfection, as described on p. 395. The person must be kept quiet in bed in a room kept at a regular degree of warmth, but yet with plenty of pure air. Draughts and chills should be carefully avoided. Bread and milk, beef-tea, mutton broth, and such mild food ought to form the diet. If the fever is high and the patient restless, a warm bath is of great service, or sponging with lukewarm water. The cough may be relieved by gargling the throat with warm milk. Sometimes sucking a small piece of ice is very grateful, but much improvement need not be expected till the fever begins to diminish. To aid in promoting the action of the skin and kidneys the following mixture is valuable:—

Solution of the Acetate of Ammonia, ...	1½	ounce.
Spirit of Nitrous Ether, ...	½	,,
Ipecacuanha Wine, ...	¼	,,
Mucilage (Solution of Gum Arabic), ...	1	,,
Water, ...	1	,,

Give from a half to one tea-spoonful (according to age) every two or three hours.

This is specially useful at the height of the fever. If convulsions occur, a warm bath should be employed.

As recovery takes place the food should gradually return to the full ordinary diet. After the disappearance of the fever, if exhaustion is great, small quantities of port wine are necessary, but not otherwise. A dose of mild opening medicine is occasionally necessary, but is to be carefully given, from the risk of looseness of the bowels.

Affections of the ears and eyes are to be treated as recommended in Section XII. B.

German Measles (*False Measles*, *Rötheln*, *Rubella*, *Epidemic Roseola*) is a disease apt to be mistaken for measles, and even scarlet fever. It differs from measles in there being little sneezing, little cough, and nothing of the red watery eyes, all of which are characteristic signs of measles. It is a different disease from measles, for, while one attack of measles protects, as a rule, from a second, an attack of false measles gives no protection from true measles, though it protects against a second attack of its own kind. It never develops into true measles, though a child may have a real attack of measles shortly after an attack of German measles. It is not so contagious as true measles. The affection does not show itself till from one to two weeks after infection.

Symptoms.—The disease is marked by an eruption, appearing first on the face and quickly spreading over forearm and hands, legs and feet, and rapidly covering the whole body. The spots are *raised above the skin*, of a dusky red, irregular in shape, and they soon run together. This eruption is accompanied by little fever. The patient may complain of a feeling of fulness of the head, of giddiness, and perhaps of some headache, in short of being a little "out of sorts," and frequently does not complain at all, the rash being attended by apparently no disturbance. Moreover, before the eruption there is often little complaint. In true measles, as noted on p. 401, there is considerable fever, with severe cough, sneezing, and other signs of cold-in-the-head, and the fever usually reaches its height when the rash appears on *the fourth day*. Now, in false measles, if there is any disturbance before the fever it is slight, and usually the rash appears *within one day, or at the most two days*, of the person feeling unwell. It does, however, sometimes happen that there is considerable fever, loss of appetite, &c., before and during the rash, and in young children the disease occasionally sets in with vomiting, diarrhœa, and convulsions. On the second day the rash is fully out, and immediately begins to disappear, fading by the third or fourth day. It is accompanied by itching, but on fading it leaves no mottling of the skin as measles, though the separation of fine scales of the scarf-skin may follow it.

Treatment.—Rest in bed for three or four days, and such mild diet as recommended for measles are sufficient treatment. The infectious character of the disease must not be forgotten, and as the infection probably lasts for some weeks, care should be taken that the disease is not spread.

Small-pox is a contagious and infectious disease. Its chief feature is the appearance of a rash on the skin, consisting first of pimples, which enlarge and become little sacs filled with clear fluid, afterwards changing into matter. Scabs form when the matter dries up, and on their fall, they leave marks or not according to the severity of the attack. There are different degrees of severity of an attack of small-pox, in-

dicated by the eruption. In the less serious form the different pocks are separate from one another, and the small-pox is said to be *distinct* or *discrete*, in a more violent form the pocks run together, and the disease is said to be *confluent*. The former kind is often fatal, the latter nearly always so. The disease, like other contagious fevers, has a period of incubation, there is, that is to say, an interval between the time when the disease is caught and the time when it begins to show itself. That period is from eight to eleven days. In all cases several stages can be recognized in the progress of the fever. These stages are—that of *invasion*, the period of the beginning of the attack, that of *eruption*, the period when the rash appears, that of *suppuration*, the period during which the contents of the pocks become matter, and that of *drying-up* or *desiccation*, when crusts form. The time of these stages may be given. As a rule the fever begins *eight or twelve days after* the disease is "caught;" *on the third day* of the fever the eruption appears; *about the eighth day* suppuration begins, and lasts till the eleventh, after which the drying-up process goes on; the scabs tend to separate *about the fifteenth*, *eighteenth*, *or twentieth day*. These are the times for the appearance, suppuration, and drying-up of the eruption *on the face*. On other parts of the body the various stages are a little later in occurrence.

Symptoms of Distinct Small-pox.—The chief symptoms at the beginning of this form are fever and constant sweating, vomiting and costiveness of the bowels, and severe pain in the small of the back.

The attack is usually sudden. The patient is seized with shivering fits (rigors) followed by great heat of the skin. The sweating is marked for several days in grown-up persons, not in children. In children also diarrhœa (looseness of the bowels) is usual and not costiveness, but in adults diarrhœa is rather the indication of a very severe attack. Convulsions are also common in children. The pain in the back is usually severe, and may be attended by numbness or paralysis of the legs and difficulty in making water. Instead of the severe pain in the small of the back, there may be dull pains throughout the body like those of rheumatism. During this time the fever runs high.

With the beginning of the *second stage*—the appearance of the eruption — the fever falls and the other symptoms disappear, so that the patient may seem to be almost well. This continues till about the eighth day, when the fever returns with the suppuration of the pocks. The eruption, as it appears on the third day, consists of small red hard points, slightly raised above the skin. They grow larger, and in the course of a day form hard prominent pimples. In the course of two more days they have become converted into vesicles, that is, small sacs or blebs containing a milk-like fluid. They go on increasing in size. On the eighth day the fluid they contain has become yellowish, and consists of matter or pus. Hence the eruption consists now of pustules, or small abscesses. On this day, also, the skin around each pock or pustule is distinctly red. There is, indeed, a ring of inflammation round each. Accompanying the inflammation there is swelling in the skin and parts beneath it. The pustules are painful and the fever returns.

The return of the fever marks the arrival of the *third stage*, that of suppuration. The pustules still increase in size, and the yellowness of their contents becomes more visible. This stage is marked also by swelling, already noted, of the parts on which the eruption is seated, which increases up to the *ninth day* of the disease, and then diminishes, disappearing about the eleventh day. It is greatest where the skin is loose, and thus is often very great on the eyelids, causing complete closure of the eyes. It is marked on the hands and feet. The fever of the period of suppuration may not be so high as the early fever. It is accompanied by shiverings, quick pulse, loss of appetite, furred tongue, and delirium. It lasts for three days, and then if the case progresses favourably, rapidly disappears, not to return, and the other symptoms with it. The pustules thereafter pass through the process of drying-up, to be noticed immediately.

The eruption does not appear all over the body at once. It begins on the face and neck, spreads to the upper part of the chest, arms, and hands, to the rest of the body later, and to the legs last. In the course of two days it will have spread over the body. But those on the face having appeared first, will always be in advance of the others, and thus those on the face may be dried up while those on the legs are only fully ripe. The eruption is also present on the lining membrane of the throat and mouth, and causes pain in the throat, felt from the commencement of the rash. It is also sometimes present on the lining membrane of the eyelids (the conjunctiva, p. 339), and may lead to serious injury of the eyes. The pocks on the body have often a depression in the centre, not seen in those on the face. Pocks showing this are said to be umbilicated.

The *final stage* of small-pox is that in which the pustules dry and form scabs. The scabs begin to fall from the face between the fifteenth and twentieth days, and a little later from the body. A red prominence is left, after the fall of the scab, on which scales form, and from which they fall for, it may be, several weeks. Finally after some months the redness disappears, and a white scar is left, below the level of the rest of the skin. If the pocks have not been large, the marks may be very slight.

Such is the history of **distinct small-pox.** It is one of the least fatal forms of the disease, except in unvaccinated children below one year of age. Nevertheless it may prove fatal even in grown-up persons. When death occurs from distinct small-pox, it happens about the eighth or ninth day. According to the French physician, Trousseau, a fatal issue is to be feared when the eruption does not come well out by the fifth, sixth, or seventh day, when the pustules are irregularly formed, when the sweating ceases suddenly and cannot be recalled, and when delirium occurs with dry cold skin and a weak, sharp, irregular pulse. Profound unconsciousness and twitchings of the tendons are signs of approaching death.

Symptoms of Confluent Small-pox.—The confluent form of the disease, in which the pocks run together, is a very fatal form. The symptoms of its commencement are similar to, but more severe than, those already described. The pains are more intense, fever more decided, and vomiting continuous. The eruption comes out earlier than in the ordinary case, appearing on the second day instead of the third, though in very bad cases the rash may be delayed. The fever is not only very high, but it does not fall for any time between the period of the rash appearing and the period of the pocks ripening, as it does in distinct small-pox. It is almost continuous till the pustules have become yellow with matter. The eruption, which, as already stated, appears early, and may at first be mistaken for measles, because of the general redness of the face, consists of small pimples extremely close set. As they grow in size great swelling of the face is produced, and when they grow into blebs, they so run together that large patches of raised skin are produced like that caused by a blister. The swelling of the face is accompanied by swollen eyelids, swollen jaws and ears, and there are constant flow of water (saliva) from the mouth, and harsh cough. The ball of the eye may be fiercely attacked and vision destroyed. The swelling of the face and the flow from the mouth should begin to diminish by the eleventh day. At the same time there occurs great swelling of the hands and feet, due to the pustules, and the swelling is accompanied by pain. When the pustules have become ripe, full of matter, which occurs between the eleventh and thirteenth day, they give out a most disgusting stench, and the patient's skin is in a most serious condition, with the leaking pustules, ulcers formed from them, and often boils and abscesses, due to some extent to the irritation of the decomposing matter of the pocks. (Plate VII.).

Delirium, in confluent small-pox, is apt to continue from the fifth day of the disease till the thirteenth or fourteenth day, when it should cease. But the fever has not such a defined period, for it may be maintained beyond the third week by the formation of boils and abscesses in the skin, and also in deeper parts. At this late period attacks of shivering, with high fever, indicate the formation of deep boils.

In confluent cases death is very common, and usually occurs between the eleventh and fourteenth days. Excessive delirium, or deep unconsciousness, great prostration, much difficulty of breathing, and anxiety, these are all bad signs. Death sometimes arises from suffocation by swelling and the formation of membranes in the throat. Inflammation of the lungs may hasten a fatal termination. But even should the patient survive this period, prostration and death are too apt to be the result of the prolonged formation of boils, &c., in the skin and deeper parts.

Black Small-pox is the most fatal form, and is so called, because, while the ordinary rash is scanty there is an eruption of dark blue, violet, or black spots. These are due to bleeding that has taken place into the skin, and in some cases blood is lost from the nose, mouth, and other parts. Such cases are accompanied by delirium and high fever and rapidly end in death.

Treatment.—As in other fevers with rash, no attempt need be made to arrest or cure an attack of small-pox. It will run its own course. All that remains for friends or doctor to do is to "stand by," and do all that is possible for the patient's comfort and for the maintenance of his strength. The patient should be placed in a large well-ventilated room. The patient must not be heavily covered. His body and his bed should be kept as clean as possible, sponging with lukewarm water may be adopted, and the bed-sheets should frequently be changed. The skin may be anointed, after sponging, with

olive-oil or vaseline. Mutton broth, milk, beef-tea, &c., should be given in small quantities frequently. Lemonade, or gingerade, or acid drinks made with dilute sulphuric acid, are grateful. If delirium and excitement are great, lukewarm baths are of use. The attendants should have been vaccinated. A patient who recovers must not be allowed to mix with other persons till all crusts and scales have disappeared, and till daily baths for a week have been taken. The utmost care must be taken to prevent the spread of the disease, as advised on p. 395. During a small-pox epidemic all unvaccinated persons should be vaccinated, and among those who have been vaccinated, but as long before as seven years, re-vaccination should be practised.

Small-pox as altered by Vaccination (*Modified Small-pox—Horn-pox*).—While vaccination, if properly performed, as a general rule protects from small-pox, yet a vaccinated person may take the disease; but it does not run the ordinary course, and the risk attending it is slight. In the same way a person who has had small-pox is protected, as a general rule, from a second attack. Yet cases do occur where the disease attacks for the second time, and in this case also it does not run its full course. In both cases the disease is altered. It is, nevertheless, the same disease, for if a person suffering from the altered form communicates the disease to an unvaccinated person, in that person it will appear in its ordinary unaltered form. A vaccinated person suffering from a mild attack of small-pox may thus communicate the disease in its most aggravated form to an unvaccinated person. (Eruption is shown on Plate VII.)

The **symptoms** of altered small-pox are up to a certain point similar to those described under distinct small-pox. The symptoms at the beginning are the same—shivering, fever, pains in the back, vomiting—but they are milder. The eruption comes out about the same time—the third or fourth day—but the pimples are few in number. They suddenly cease to progress in the usual way, and soon disappear. Or the eruption comes out as usual, progresses to the stage of forming blebs, and then dries up without any fever of suppuration. Even when the pocks reach a more advanced stage, swelling of the face, of the hands and feet, and other symptoms of the bad forms of small-pox are scarcely ever seen in small-pox altered by vaccination. In short the disease never gets a proper hold of the person. It may flourish for a few days, but speedily looses its hold and convalescence begins. Just as some seeds sown in particular kinds of soil may never produce good fruit, because the soil is deficient in the particular kind of nourishment they need, so that they spring up and progress to a certain stage only to wither away, so, in a person who has had small-pox previously or has been vaccinated, there seems to be a want of the particular elements in the blood and body on which the small-pox poison flourishes. They either are, on that account, unable to take a second attack, or, if they take it, the disease advances only a little way and then abruptly terminates.

Inoculated Small-pox.—Long before vaccination was known it had been observed that persons who were inoculated with small-pox, into whose skin, that is to say, the small-pox poison was deliberately inserted, suffered usually from a milder form of the disease than those who caught the infection in the ordinary way, while at the same time they were protected from another attack. It appears that the habit of inoculating small-pox was practised from time immemorial in Persia and China, just because small-pox was so common that few could escape it, and because the attack was less likely to be fatal when deliberately communicated in this way. An English lady, Lady Mary Wortley Montague, observed the practice while residing in Constantinople in 1717, and had her son of six years of age inoculated with success. Returning to England she announced the practice in 1721, and had it performed with good result upon her daughter. As a result the practice spread, but met with much opposition. But after a time it was accepted, and generally performed till vaccination was introduced.

On the second day after matter from a small-pox pustule has been introduced under the skin of a person, a pimple appears at the spot. By the fourth day it has become a bleb, and by the seventh or eighth the milky fluid in the bleb has become matter, that is, the bleb has become a pustule. It is surrounded by a red inflamed ring, which increases up to the tenth day, and on which a number of smaller pustules appear, round the large one, which also increases in size. It is not till this time that any signs of general disturbance appear. But now shiverings occur, fever arises, headache and pains in the loins are felt, and there is vomiting—the usual signs of the beginning of an attack of small-pox. On the eleventh, twelfth, or thirteenth day after the

inoculation the ordinary small-pox rash appears, which follows the course described under **distinct small-pox.**

Small-pox so produced is infectious, and an inoculated person might, therefore, originate an epidemic. Moreover, though usually mild, it was sometimes disfiguring and fatal. One can, then, understand how, at one time, the disease was feared and dreaded, when persons would run the risk of being inoculated rather than take the chance of escaping infection in the ordinary way. This is one of many facts of which the agitators, who denounce vaccination, are surely ignorant.

Vaccination (from Latin, *vacca*, a cow. *Cow-pox*). (Plate VI.) In spite of inoculation, practised as described in the preceding paragraphs, the mortality from small-pox seemed to be on the increase in Britain, when, in 1798, Edward Jenner, a surgeon practising in Gloucestershire, published an inquiry into the causes and effects of cow-pow.

Cow-pox is a disease of oxen, manifested by the appearance, usually on the teats and udders of cows, of pocks, which almost exactly resemble those of small-pox. There is also a disease of the horse, called **horse-pox,** supposed to be the same disease to which the term **grease** is applied, which is believed to be the same disease as cow-pox. Cow-pox is a contagious disease, and is liable to break out as an epidemic among cattle. Now, anyone who milks a cow, suffering from this disease, is liable to get on the hands some of the matter from the pocks, and if by a scratch or other pathway the matter can pass into the system of the person, that person is likely to contract the disease, which will show itself by the appearance of pocks at the infected parts, but by no other symptoms of any consequence. It had been for long a tradition among dairy-folks that anyone who had thus contracted cow-pox was safe from the risk of an attack of small-pox. This notion Edward Jenner had become aware of while still an apprentice to a surgeon, and it took firm hold of his mind. For years he did not cease to think of it, to inquire concerning its truth, to make observations and experiments as well. For thirty years he worked quietly at the subject, and then he published his work on cow-pox, which completely established the truth of the old and vague idea, and raised it at once to the rank of a scientific fact. He gave details of persons who had accidentally contracted cow-pox, and who had remained proof against the infection of small-pox. He showed that persons who had thus been accidentally vaccinated were safe from small-pox even when small-pox matter was deliberately introduced into their bodies. He did more. He took matter from the pocks of a cow and introduced it into the skin of a child. In time this child showed the pocks of vaccination, now so familiar to every one. With matter from this child he vaccinated a second, and with matter from the second he vaccinated a third, and so on through five generations. Then into the body of the child vaccinated last *he introduced small-pox poison and found it proof against the disease.* This was convincing evidence that the matter of the cow-pox could still protect from small-pox even after it had passed through the systems of many persons in succession. It was not, therefore, necessary to go back to the cow for matter. After the publication of Jenner's work his statements were subjected to tests of the utmost severity, and were found to be perfectly unassailable. Thus at the London Small-pox Hospital, in the two years following that of Jenner's publication, 7500 persons were vaccinated, and about one half were afterwards inoculated with small-pox poison without the slightest effect.

Course of the Vaccination Pocks.—When a person has been properly vaccinated, nothing appears where the matter has been inserted till the second or third day, when a small red pimple shows itself. This grows larger and becomes, by the fifth or sixth day, a rounded greyish bleb filled with clear fluid, and usually not raised in the centre. It goes on becoming larger till the eighth day. After this the clear contents begin to become yellowish, the skin round the pock becomes red, inflamed, and thickened, and by the tenth day the skin for some distance round the pock is deeply red and hard, and the contents of the pock have become yellow matter. The pock now begins to dry up, and the inflammation and hardening round about to lessen, till by the fourteenth or fifteenth day the pock has changed to a dry dark scab, which falls about the twentieth day or a few days later, leaving a scar in the skin presenting numerous little pits, the surrounding inflammation having disappeared. If the vaccination has been successful the scar remains for life, and is easily recognized. A scar not well marked means imperfect vaccination; and, of course, the degree of safety from small-pox varies with the degree of effect which the vaccination matter has produced in the body of the person. During the progress of the pocks the person exhibits

signs of being generally affected, but not, as a rule, before the eighth day. There is some degree of feverishness, restlessness, irritability, and disturbance of digestion, which soon pass off, but still indicate that the vaccination has produced more effect than simply a pustule at the place where the matter was inserted. If the pocks do not pass through the stages described, if, for example, a scab is formed on the fifth or sixth day which soon falls, the vaccination is not perfect and the protection is not complete.

Now the same pocks are produced whether the matter has been taken direct from the cow or from a person previously vaccinated.

The matter intended for vaccination should be taken from the cow or from the human being *on the eighth day*, while it is still clear and transparent.

Mode of Vaccination.—One of the most valuable parts of Jenner's work was the proof that the matter of the cow-pox could be passed through human beings for many generations without its value being lessened. From each fully grown pock sufficient matter can be obtained to vaccinate about a dozen persons. When the pock is opened by the fine point of a clean lancet, the clear fluid runs out, and this fluid may be placed on the skin of an unvaccinated person from the lancet point, and caused to enter the blood by the point being passed into the skin sufficiently deeply to reach the true skin. A simple method consists in making a series of scratches across one another (as in Fig. 181), with the clean lancet point, on the part of the skin where the matter is placed. The scratches should be just deep enough to show blood. If they are too deep, the flow of blood may wash the matter away. The upper part of the arm is usually chosen. The matter may be kept for any length of time in properly sealed tubes. Extremely fine hair-like tubes are used. When the end of the tube is placed in a drop of the fluid, the matter passes up by attraction, and when the tube is thus three-parts filled, the ends are sealed in a flame. Or the matter may be placed on small slips of glass or on clean quill points and allowed to dry. When the matter is required for use, the ends of the tube are broken off and it is blown out on to the skin, or the plates or quills are moistened with a small drop of pure water and rubbed on the skin where the scratches are made. Thus from one good pock sufficient matter may be preserved to vaccinate half-a-dozen or a dozen persons.

Fig. 181.

Objections to Vaccination.—It might have been supposed that when Jenner had conclusively shown the value of his practice, and when cases by the thousand and tens of thousand confirmed his views, and proved that by means of vaccination a hateful disease, which killed thousands annually and mutilated for life many thousands more, could be rendered practically harmless, it might have been supposed that the acceptance of the practice would have been universal. But it was not so. Objectors rose on every side, and the more successful the method was shown to be the more vigorous became the opposition. One set of objections was sentimental. It was maintained that with the cow-pox some of the disposition of the ox would be imparted. It was declared that the moral character of children became perverted, that they exhibited the effects of a "bestial humour," that as vaccination was carried on the human race would degenerate, that innumerable evils would arise, that innumerable new and unheard-of diseases would appear, that brutal tendencies would appear in vaccinated children, and that even brutal features would show themselves, in the appearance of horns, hair, perhaps tails, in the expression of the voice, which would become bellowing, in the character, which would become bullying. Pamphlets and doggerel rhymes of the wildest description were published to throw discredit on the practice. The following verses from one of these sufficiently show the nature of this opposition:—

O Jenner! thy book nightly phantasies rousing,
Full oft makes me quake for my heart's dearest treasure;
For fancy, in dreams, oft presents them all browsing
On commons, just like little Nebuchadnezzar.

There, nibbling at thistle, stand John, Jem, and Mary,
On their foreheads, O horrible! crumpled horns bud;
There Tom with his tail, and William all hairy,
Reclined in a corner are chewing the cud.

Another kind of objection was of the pious sort. Small-pox was a "merciful provision on the part of Providence to lessen the burthen of a poor man's family;" it was impious to attempt to set aside a divine dispensation; &c., &c.

There were other and more serious objections. It was urged, and proofs were offered in support of the statement, that vaccination did not give the protection asserted, that many vaccinated persons were seized with small-pox, that vaccination so affected the system as to lay it open to such diseases as consumption, scrofula, &c., and that, with the vaccine matter, the poison of such diseases as syphilis might be and was introduced. The result of these more scientific

objections was to rouse the supporters of vaccination to the fullest and most far-reaching inquiries. Medical colleges and medical men were appealed to in every civilized nation, and as a consequence a body of evidence in favour of vaccination was produced, which to this day stands unassailed and unassailable, fitted to convince every rational mind that vaccination, *if properly and universally employed*, affords a method of completely stamping out small-pox from the face of the earth. Anyone who chooses to examine the question for himself will find the facts in "Papers Relating to the History and Practice of Vaccination," presented to the British House of Commons, and published in 1857. Some of the most striking facts may be given. It is estimated that in 100 years before the introduction of vaccination, 45 millions of persons died in Europe of small-pox. In Greenland in 1734 two-thirds of the population were swept away by an epidemic. In Iceland in 1707 it destroyed 18,000 out of a population of about 50,000. In North America one tribe of Indians, numbering 1500 persons, all perished by its ravages excepting only thirty. It is estimated that in the Russian empire alone it had *annually* two millions of victims. After the introduction of vaccination the death-rate from small-pox fell at once, and diminished just in proportion to the thoroughness and extent of the practice. In Sweden, before its introduction, small-pox had annually 2050 victims, after its introduction only 158; in Berlin for 24 years before its introduction the deaths from small-pox were 3422 annually, for 40 years after its introduction the annual death-rate fell to 176; in London the annual deaths from small-pox before vaccination were 3000 to 5000, after its introduction they were under 340. It is to be remembered that these results were obtained when vaccination was not nearly universal, and that the deaths were chiefly among non-vaccinated persons.

It appears, however, quite true that the protection from vaccination is not absolute. That is to say, there have been cases where persons properly vaccinated have yet contracted small-pox, but *in every case the disease was so mild as to cause little risk of death.* Such cases are, however, rare. It was abundantly proved that the very large proportion of cases brought forward of persons who had contracted small-pox after vaccination, were really cases in which the vaccination had been improperly performed. It was shown that matter, in no sense true vaccine matter, might be used which would produce irritation at the point of insertion and set up inflammatory changes, which ignorant persons might suppose to be the vaccine pocks, but were not so. Such false vaccination could not give protection. While this was proved, it is admitted that in a few cases, indeed a very few cases, proper vaccination may not completely protect from small-pox, though it renders the disease extremely mild. But then there are undoubted cases on record where one attack of small-pox itself does not confer complete protection from a second. Indeed it would appear that the protective power of efficient vaccination is of the same extent as the protective power of a previous attack of small-pox.

The explanation of the protection accorded by small-pox is one that was surmised by Jenner himself. Numerous positive experiments go to show that the pocks of the cow and the small-pox of man, as well as (apparently) the pocks of the horse, are due to one and the same poison operating with different degrees of violence on different animals. Thus Mr. Ceely, a surgeon of Aylesbury, began a series of experiments in 1839, which went to prove that small-pox poison introduced into the body of a cow produced cow-pox. Thus, in one case, he introduced small-pox poison into a stirk. At the place of puncture the cow-pox appeared by the sixth day. From one pock he took matter with which he vaccinated several children, and in the children it produced the appearance of ordinary vaccination pocks. He passed this matter through several generations in children, and obtained a supply of matter which was used in the Small-pox Hospital and Cow-pox Institution of Dublin, and gave all the results of ordinary vaccination. Thus small-pox of the human being became cow-pox in the cow, and the matter of the cow-pox, when transferred to the human being, became the vaccination-pox. It thus appears that vaccination protects against small-pox because it is, as regards the poison producing it, the same disease, but deprived of its violence and extremely poisonous character by previous passage through the cow. Therein lies the reason why vaccination cannot protect more absolutely against small-pox than small-pox itself.

As tending to show how the objection that vaccination does not give complete protection against small-pox is rather an argument against imperfect vaccination, one or two facts may be given in the form of a table. The table is based on the observation of 5000 cases of small-pox received in the Small-pox Hospital of London. It states the death-rate among different classes

of patients: (1) the unvaccinated, and (2) the vaccinated. But the vaccinated have been divided into different sets according to the number of vaccination marks or scars found on their persons.

Of unvaccinated, there died ...	35	out of every	100
Of those said to be vaccinated but having no mark, there died about	23	,, ,,	100
Of vaccinated—			
Showing 1 mark, there died nearly	8	,, ,,	100
,, 2 marks, ,, ,,	5	,, ,,	100
,, 3 ,, ,, ...	2	,, ,,	100
,, 4 ,, ,, ...	1	,, ,,	200

These figures are confirmed in the experience of other hospitals. It appears thus that the more thorough the vaccination the more complete the protection, and that that amount of vaccination is safest which leaves four well-marked scars.

It has been shown that the protective power of vaccination diminishes after the lapse of years. That objection is easily met. It is only necessary to have the vaccination repeated whenever necessary. (See RE-VACCINATION, p. 410.)

The gravest objection that has been urged against the practice is that vaccination has, in many cases, been the direct cause of serious disease. It is quite true that carelessness and want of cleanliness on the part of parents towards their vaccinated children may result in serious inflammation, erysipelas (rose), &c., of the vaccinated arm. But filthiness will render a pin-scratch a serious affair, and it is monstrous to suppose that parental neglect is to be an objection to a method for protecting the lives, not of one here and there, but of the whole community from a disgusting and fatal disease. Unfortunately there can be no doubt that syphilis has been communicated by vaccination. It has been shown, however, that pure vaccine matter taken from a syphilitic child cannot communicate syphilis to another child. It is only when the vaccine matter *is mixed with the blood* of the diseased child that risk arises. There are, therefore, two safeguards against such a danger, one is the evidence to the eye that the matter about to be used has no trace of mixture with blood, the other is due care in the selection of a healthy child from whom the matter is to be obtained. In short, care on the part of both parent and vaccinator are two absolute safeguards against the possibility of any danger arising from the practice.

But it would require proof of even greater dangers to justify any attempt to set aside a practice which has effectually subdued a disease that has swept away whole populations, and has every now and again made attempts to reassert its old evil dominion. The compulsory adoption of the practice is justified by the fact that every unvaccinated person is a danger to the community in which he lives. If the person who refused to be vaccinated endangered only himself he might be left till time and small-pox taught him his folly, but when it is remembered that every small-pox patient may be a source of infection to multitudes, a community is entitled to decree that no man shall be permitted to dwell in its midst without adopting the recognized precaution against the disease. "The wheel of time brings back the follies of the past oftener than its wisdom," and objections that were met and answered two-thirds of a century ago still find people prepared to urge them. Anyone who carefully examines the many documents on vaccination that are open for reference, can arrive at this conclusion only, that the opposition to vaccination can find supporters only among the grossly ignorant or the wholly irrational.

Rules for Vaccination.—Every child ought to be vaccinated within a very few months after birth. If the child is well and strong it is good to have it done by the third month, before the troubles of teething begin. *If, however, small-pox be in the neighbourhood no age is too early.* If the child be sickly or recovering from some sickness it ought to be postponed for some weeks till strength returns. Not less than two well-marked pocks should be produced, but four give the greatest degree of safety. Many people prefer to have their children vaccinated with matter from the cow, and there is, of course, no objection to this if the child be vigorous. For it is to be noticed that the effects of the cow's matter are more marked than those of matter passed through the human subject. But if the child from whom the matter is taken is thoroughly healthy there is no risk in the use of such matter, and it is as effective for the purpose. The arm which has been vaccinated should be carefully protected from rubbing and injury, and perfect cleanliness observed. Care should be taken that clothes do not press unduly up into the armpit to interfere with the natural flow of blood in the part. Many people employ shields for protecting the parts from rubbing. This can be quite as well done without such a contrivance. Moreover, the tapes used for tying on the shields are seriously apt to interfere with the circulation and cause a much more than usual degree of swelling in the arm. Wherever small-pox is prevailing all persons above ten at the utmost,

who were vaccinated in childhood, should be re-vaccinated, and naturally no time should be lost in having vaccination performed on any who have never undergone the procedure.

Re-vaccination. — It is extremely desirable that all persons who have been vaccinated in childhood should be vaccinated again before the twentieth year as a matter of course, but where any risk of infection is present, the second vaccination should be performed by the tenth year. Small-pox among adults who have been re-vaccinated is practically unknown. But, after the lapse of years, the protection against small-pox to those who have undergone the process only in childhood diminishes, though if they were attacked the disease would always be milder.

Chicken-pox (*Varicella*) has been supposed to be a mild form of small-pox. It is not so, for an attack of small-pox does not protect against chicken-pox, nor the latter against the former, although one attack of chicken-pox protects against a second. It is highly infectious; and children mainly suffer. The infection is caught from one to two weeks before the disease shows itself. That is, its period of incubation or hatching lasts that time.

Symptoms. — The disease shows itself by some degree of feverishness, restlessness, loss of appetite, and within twenty-four hours rosy-red pimples appear on the face, head, chest, and other parts of the body. These speedily become blebs, filled with clear fluid and surrounded by a ring of inflammation, enlarging till they may be equal to the size of a split pea. Within a week the blebs pass through the stage of pustule, that is, the clear fluid becomes changed into yellow matter, and dries up into dark-coloured scabs. By another week the scabs have fallen, leaving red marks, which last for a time. The rash does not come out all at once, but in crops, so that for three or four days one set follows another. They may appear on the sides of the mouth and tongue. In ten days or a fortnight the disease has run its course. The disease has no evil results, though the child may remain weakly for some days after its disappearance. (Eruption is shown on Plate VII.)

Treatment.—The child should be kept in one room, and have ordinary mild diet, milk, &c. No medicine is necessary. Separation from other children ought to be insisted on, as the disease is so infectious.

Typhus Fever is a very infectious fever. The infection seems to come off from a patient in the breath, and not, as in typhoid fever, in the motions from the bowels. The infectious matter, however, does not seem to thrive in the open air, nor does it attach itself to clothing, &c., or retain its poisonous characters as that of scarlet fever does. For free ventilation and plenty of fresh air are not favourable to the spread of typhus. It is probably for this reason that typhus is largely a disease of the poor, especially of the poor crowded together in small, ill-ventilated, and dirty houses. It is specially common in overcrowded parts of the poorer districts of towns in Great Britain and Ireland. It attacks both sexes almost equally, and at all ages, though the majority of those attacked are between the ages of ten and thirty. The greatest number of cases occurs during the winter and the smallest during summer, perhaps because in the winter the very poor huddle together for warmth, and the condition of overcrowding is thus readily produced. It usually attacks the same person only once, although there are cases of the same person suffering from it twice or even thrice.

Symptoms.—Between five and twelve days may pass after the person is infected before the symptoms of the disease appear. The first symptoms are shivering, headache, loss of appetite, thirst, and perhaps sickness, general weakness, quick pulse, and increased heat of skin. The bowels are bound. A noticeable symptom is dulness and heaviness of the patient, who has a stupid confused look, and cannot fix his mind upon anything; and sleep is disturbed. About the fifth or seventh day the rash comes out (Plate VI.). It is apt to be mistaken for measles, but the spots, which are of a dusky red colour, are not so large and raised as those of measles. It appears first on the sides of the chest and belly (measles appears first on the forehead round the edge of the hair), and on the hands, wrists, and elbows, spreading over the body, arms, and legs in a couple of days, but not marked on face and neck. After coming fully out it remains out for two or three days, and then begins to fade, disappearing by about the fourteenth day. In bad cases dark-coloured spots, due to the escape of small quantities of blood in the skin, may be present after the true rash has faded. During the second week of the illness the symptoms become worse. Delirium becomes constant, though, if sharply spoken to, the patient may be recalled to himself for a moment. Sometimes the delirium is violent, sometimes of a low muttering kind. As the disease progresses the tongue becomes dry and brown, the pulse faster and weaker, and the general weakness so marked

that the patient lies well down in the bed, on his back, with mouth and eyes half open, and motions and water are passed in the bed unconsciously. Often the hands wander aimlessly about, picking at the bed-clothes, a sign of great prostration. About the fourteenth day, in favourable cases, the turn of the fever is shown by the patient falling into a gentle sleep, from which, after some hours, he awakes quite sensible, with the fever almost gone, but in a state of extreme weakness. With careful nursing he goes on showing signs of improvement in returning appetite and gradually increasing strength, so that at the end of three or four weeks he is quite restored. If the case is going to end unfavourably the prostration increases, and instead of the turn at the thirteenth or fourteenth day, deep unconsciousness sets in, the fever runs up, and the patient sinks under it. Convulsions may occur, in such a case, before the unconsciousness comes on. The case may be milder than has been described, the delirium being limited to a "wandering," or it may be much worse, death taking place within the first week, instead of towards the end of the second, the usual time in fatal cases.

Ten out of every hundred is about the death-rate in typhus fever, and the deaths under twenty are fewer than those above it.

The chief complication in typhus is congestion of the lungs, largely brought on by the intense weakness produced by the disease.

Treatment.—The patient should be treated in a large well-aired room, fresh air being in this case the best disinfectant. He should be kept strictly to bed to reserve the strength. For maintaining the strength careful feeding is necessary. Sips of milk, beef-tea, nourishing soups from which all vegetables have been strained off, should be given *at short intervals.* The patient will in this way be induced to consume a large quantity in twenty-four hours, which he would not otherwise take. Thirst is to be relieved by barley-water, lemon-juice in water, or plain water. An occasional dose of castor-oil may be necessary to relieve the bowels, and at proper intervals the patient must be told to make water, since the intense listlessness of the patient may lead him to fail to do so. Sometimes the water requires to be drawn off. *The patient must never be left unwatched.* Delirium, which sometimes needs restraint, is to be met mainly by quiet, darkening the room, and applying cold cloths to the head. Stimulants, though not always necessary, are sometimes of great use towards the end of the second week, when the weakness is extreme, specially if the pulse is very fast and weak. They are doing good if the pulse becomes less frequent and stronger. The best stimulant is perhaps wine, to be given in tea-spoonful doses at intervals to the extent of two wine-glassfuls in twenty-four hours, or brandy or whisky in milk, half a wine-glassful to be mixed with a breakfast-cupful of milk, and given in doses of two or three tea-spoonfuls at a time, the whole cupful to be given in twenty-four hours. If cough, spit, and increased difficulty of breathing indicate congestion of the lungs, stimulants are to be used in this way. Twice the quantity noted may, in such a case, be given in twenty-four hours if it seems doing good. During the period of extreme weakness the attendant must guard against bed-sores by keeping the patient scrupulously clean, and by changing his position occasionally, so as to prevent the same parts being constantly pressed upon. During recovery strength is to be aided, not by stimulants, unless really necessary, but by careful nursing and feeding, frequent small quantities of nourishing beef-tea, soups, &c., being given.

Typhoid Fever (*Enteric Fever—Intestinal Fever—Bilious Fever—Gastric Fever*). Up till 1840 two fevers were confounded under the term *typhus* fever, but that two essentially different diseases were included under the one name was pointed out at the time mentioned by Dr. A. P. Stewart. Later a complete distinction was drawn between the two by Dr. William Jenner, the one described in the preceding paragraphs retained the name typhus, and to the other, because it was very like typhus in many particulars, the name *typhoid* was given. This fever (typhoid) is accompanied by serious disease of the bowel, and consequently to it the name enteric fever (from *enteron*, Greek for the bowel) has been given by some who do not like the confusion that two words, so like one another as typhus and typhoid, may occasion. The phrase "intestinal fever" is thus simply another phrase for "enteric" fever. Further, this fever is marked by sickness and by very decided diarrhœa or looseness of the bowels, and thus as the symptoms marked out the stomach and bowels as the chief seats of the disturbance, the name *gastric* fever has also been used for it. This term is not now being used by modern physicians, for it is essentially a bad one. Typhoid fever is an extremely serious and a very commonly fatal disease, but there may be many

disturbances of the stomach, accompanied by fever, but attended by no risk, to which the term "gastric fever" might be applied by some. It is a matter of the utmost moment that wherever typhoid fever exists it should be discovered; and the use of any term that would in any way tend to disarm suspicion as to the true nature of the disease is undesirable. It is quite certain that two diseases are very often confounded under the phrase gastric fever, namely, gastric catarrh (described on p. 158) and typhoid or enteric fever. Typhoid fever is often accompanied by severe vomiting, in which bilious matters are vomited, and hence some have called it *bilious fever*.

The cause of typhoid fever is almost certainly some living organism or germ, such as have been described on p. 393. No one, however, has as yet been able to separate the actual living thing which produces it. There is, nevertheless, sufficient evidence to lead to the conclusion that the poison of typhoid fever is not cast off from the body of the person sick of the fever, by the breath or by the skin, as occurs in measles, scarlet fever, and small-pox. This disease is, on this account, not infectious in the same way as the others mentioned are. It seems quite clear, on the other hand, that the typhoid fever poison is cast off from the bowels in the motions passed from them. It is also clear that the poison consists of living particles, and that, if they cannot live and multiply in the air, they can and do multiply in water. Thus the discharges from typhoid fever patients, cast into drains, find in the pipes and cesspools, particularly if they are not properly flushed with water and if they are blocked so that the refuse is stagnant, most favourable circumstances for their growth. It is also certain that drainage from a dung-heap, on which discharges from a case of typhoid fever have been thrown, getting into a well, can poison the water so that every one who drinks of it is liable to be attacked by the fever. It has been proved to be thus that typhoid fever suddenly appears and spreads among the population of a town, becomes, that is to say, epidemic. Happily the causes of such epidemics have been carefully traced. The history of them has been discovered again and again, and it is commonly something like the following. In a dairy farm one of the persons takes ill of fever, and is ill for several weeks at least. There is no particular medical attendance, and the character of the fever is not known by the farm people. The discharges from the sick person are thrown on to a dung heap or thrown out carelessly anywhere. Drainage from this gets into the well. The water from the well is used to wash the milk vessels, and probably to dilute the milk, and the milk is sent into the neighbouring town. The fever poison has multiplied in the well, has got into the milk with the water, has multiplied in the milk, and has been thus introduced into the stomachs of a certain number of the townspeople, among whom, in a short time, there is an outbreak of the fever. If, then, typhoid fever is not infectious in the same way as measles, scarlet fever, &c., it is at least infectious to this extent, that people eating food or drinking water, milk, &c., containing the poison are likely to take the disease. These facts are of immense practical importance, since they show that a person may attend on a case of typhoid fever without fear, if care be taken that all discharges from the patient, and all linen soiled with them, are carefully disinfected and disposed of.

Typhoid fever may occur at any age, though it becomes less frequent as age advances. No class or condition of men is free from its attack. It is most frequent in warm seasons of the year, and least frequent during cold weather.

It appears that some persons are able to resist the influence of typhoid fever poison much more successfully than others, so that not only must the poison be introduced into a person's body, but the person must be in a favourable condition for its growth within him. A lowered state of general health, from whatever cause arising, is undoubtedly one of the most favourable conditions for the attack of this disease as of many others. While one attack of the disease seems to afford some protection against a second, many second attacks have been recorded.

Symptoms.—It is uncertain what time elapses between the period of the introduction of the poison into the body and the commencement of the disease. It appears to be about three weeks. The disease usually begins by the person feeling unwell, and losing appetite. The loss of strength and general feebleness are marked. He complains of feeling chilly and then of feverish turns, of being drowsy, troubled with headaches, and of restless sleep at night. These are all vague general symptoms. But there are also disorders of the stomach and bowels, vomiting and looseness. These are often the most striking symptoms, and should make one suspicious. The temperature of the person should be taken. It will be found higher than usual (see p. 10). The pulse will be found fast, and the tongue

coated and brownish down the centre. One symptom should be tried for. It is pain on pressure in the right groin. If one presses this part with the fingers, generally gurgling will be felt, and the patient complains of some degree of pain. If the bodily heat be determined by the thermometer as described on p. 10 it will be found that the fever is highest at night and is lower in the morning. This daily rise and fall of the fever is peculiar to this disease. The rash comes out in the second week of the disease. It consists of rose-coloured spots about the size of a pin's head, raised above the skin, found principally on the chest, belly, and back. (They are represented on Plate VI.) They come out, only two or three at a time, in crops, and they fade in three or four days. But one crop after another continues, till the end of the third week. At this period (the second week) the tenderness of the belly and looseness of bowels are more marked. The motions may be very frequent and resembling pea-soup. The other symptoms continue, and the tongue is dry and tends to crack on the surface. Towards the end of the second week the fever continues, the tongue is more dry and brown, pulse faster and more feeble, the person grows dull and listless, is very prostrate, and there is delirium. The delirium may be violent, or simply rambling, or muttering. In the course of the third week the weakness becomes excessive and bed-sores are apt to form. The patient tends to slip down in bed. The body is wasted, the lips trembling, the pulse is extremely feeble and quick. Irregular starting of the limbs occurs, and the hands wander aimlessly about, picking at the bed-clothes. Blood is frequently passed in the stools. If the case is going to end in death, the starting of the limbs and wandering of the hands are marked, the motions and water are passed unconsciously in bed, and stupor comes on. A favourable turn is indicated by a gradual fall in the fever, a less frequent and more distinct pulse, a passing off of delirium, cleaning of tongue, and stoppage of looseness of the bowels. Recovery is always gradual and very slow. Many months may occur before strength is re-established. Relapses are not uncommon, attended by rash and all the other symptoms of the disease. They occur usually about ten days after the disappearance of the fever of the first attack.

While the symptoms that have been described are those of a typical case of typhoid fever, it must be observed that cases are very numerous where the symptoms are very obscure, and where, in consequence, the disease is apt to be overlooked. A patient, for example, may complain of chilliness and feverishness, of headache and unaccountable wearied-ness, of loss of appetite, and sleeplessness at night, and may exhibit no marked looseness of bowels, no spots on the skin, and no symptom pointing out typhoid fever with any certainty, while it is this disease which is attacking him. He may fight against his feelings of illness for seven or eight days, and then speedily succumb to the disease. Perhaps some great and sudden discharge of blood from the bowels occurs, or other grave sign of the mischief going on in the bowels. In all such cases the vagueness of the symptoms must not be allowed to make one indifferent. If the temperature is taken as advised (p. 10) it will probably give such warning as ought to lead to the person being sent to bed and being subjected to careful nursing and watching.

The **complications** of typhoid fever are numerous. The looseness of bowels indicates serious mischief there. It is found that the bowels are the seat of patches of ulceration occurring in the position of the glands of Peyer (p. 140). Now, in the process of ulceration a blood-vessel may be opened and fatal loss of blood may occur. The bursting of the vessel may be due also to improper exertion or to the taking of some hard food. In severe cases the blood is passed unaltered or in clots. Usually it is altered and makes the motions black and offensive. Where the loss is sudden and great it is known by the sudden paleness of the patient, and the failure of the pulse, and fainting. Bleeding may occur between the middle of the second and the end of the fourth weeks. Another danger is that the ulceration may eat through the bowel wall into the cavity of the belly, and there set up fatal inflammation (peritonitis, p. 190). It is shown by rapid swelling of the belly, violent pain, vomiting, great anxiety of the patient, and extreme frequency and feebleness of pulse. This occurrence is most common in the third, fourth, and fifth weeks of the disease.

Congestion and inflammation of the lungs are also exceedingly common.

Treatment.—As has been already said, many cases of typhoid fever present no marked symptoms. Nevertheless every suspicious case must be treated with watchfulness, and the mild cases with the same care as the severe. The patient should be put to bed and kept there. Often a person feels so comparatively well in the morn-

ing that he wishes to get up for a little. *This must on no account be permitted.* The patient should be daily sponged with lukewarm water, and the body and bed linen must be kept clean and dry and frequently renewed.

Perhaps the most important thing in the treatment of the case is the dieting. Only soft or liquid foods are allowed. Milk in abundance, beef-tea, light mutton broth, boiled bread and milk, lightly boiled egg switched, corn-flour, &c. &c. If the bowels are loose beef-tea tends to make them worse. This is to some extent corrected by the addition to it of rice, or thickening with corn-flour. *Overfeeding must be guarded against.* If the motions are mottled with white curd of milk, the quantity of milk supplied must be reduced at once, as these curdy lumps will seriously disturb the already inflamed bowel. *It is always best not to permit the patient to have much food at one time, but to give small quantities often.* Thirst afflicts the patient, and ordinary water in moderate quantities is not to be refused. Barley-water may also be given, and water made slightly acid with dilute sulphuric acid or ordinary vinegar.

As regards drugs, opening medicines must be cautiously given. At the very beginning a good dose of castor-oil may be administered. The ulceration going on in the bowel must be remembered, and if, later, the bowels require relief, it is best to give an injection of soapy water or weak tea of chamomile flowers. Looseness of the bowels, if excessive, is to be checked by the catechu and chalk mixture, with the addition of laudanum, if necessary, to a grown-up person. (See PRESCRIPTIONS—CHALK MIXTURE.) Bleeding from the bowels is restrained by a half to one tea-spoonful of liquid extract of ergot (spurred rye) if it is obtainable, to be given every two or three hours, as long as required. Failing that, 10 to 15 drops of turpentine every three or four hours, for several doses, may be given in a little olive-oil. Dilute sulphuric acid (10–15 drops) may also be given instead of these. If pain and swelling of the belly occur, the remedy is laudanum, 25 drops in water, repeated every two or three hours, to keep down pain. As to stimulants, they are never to be given as a matter of course. They are valuable only in the later stages of the disease when weakness is excessive, the pulse exceedingly feeble, &c. In such a case whisky or brandy is the best. It should be given in the following way: a wine-glassful of whisky is mixed with a breakfast-cupful of milk. Three or four tea-spoonfuls of the mixture are given at such intervals that the total quantity is not all used up for twenty-four hours. In extreme cases double this quantity may be necessary. But it should always be given in the way described, as thus one knows exactly how much is being given. The vessel containing the whisky and milk should of course be kept covered.

For weeks after the disappearance of the fever great care is necessary. Even in mild cases the person should on no account be allowed to sit up for a week after complete disappearance of fever, as shown by thermometer (p. 10). Even weeks after apparent recovery, improper exercise or improper food may lead to serious mischief in the bowel. All hard food should therefore be avoided for weeks after recovery.

These directions have been given for the benefit of any who may be in circumstances in which medical advice cannot be obtained. But the difficulties and dangers of typhoid fever even in its mildest form are so grave that only physical impossibility to obtain competent advice can justify any unskilled person attempting to take charge.

The fact that typhoid fever is contagious by means of the discharges from the patient must not be forgotten. Care must be taken to disinfect them in the manner described on p. 396. All linen also must be disinfected. In the country special pains must be taken that the discharges are not thrown where they may find their way into wells or burns from which a water supply is taken. It is in this way that contagion is spread, if the polluted water is used for domestic purposes.

Dandy-fever (*Dengue, Three-day Fever, Break-bone Fever*).—This is an infectious fever, not known in Great Britain, but occurring in India, Burmah, Egypt, Persia, North and South America, and the West Indies. It was first recognized in Rangoon in 1824, when it broke out among a body of troops. It attacks persons of both sexes and of all ages.

Symptoms.—The fever presents symptoms resembling rheumatic fever, scarlet fever, and ague. It often begins suddenly with severe pain in some joint, specially a finger joint. The pain jumps from one joint to another, soon attacking many. There are high fever with shiverings, loss of appetite, great weariness, sickness, and pain in the head and eyeballs. The rash comes out on the third day and is like that of scarlet fever, the face being red and puffy, the throat red and

sore, the eyes red, and a general redness being over the body. It is usually accompanied by itching. The pulse is frequent, breathing is quick, and the tongue is covered with a white coating out of which red points project. On the fifth or sixth day the rash passes off, and the fever falls, and comparative health is restored. This lasts, however, only for from two to four days, when the fever returns, and a second rash resembling measles or nettle-rash (p. 314) appears. The second attack lasts two or three days and gradually passes off, much of the scarf-skin often separating. Though the fever passes off, the pain and swelling of the joints, especially in the smaller ones, remain, and may continue to afflict the patient for weeks. Further, more than a second relapse may occur, making recovery slow and doubtful. In ordinary cases, however, eight days is the average length of the disease. In the course of the fever delirium, in children convulsions, may occur.

Treatment.—Gentle movement of the bowels should be regularly obtained, but there should be no purging. The ammonia and ether mixture (see PRESCRIPTIONS) should be given in tea-spoonful doses every two or three hours. The addition of tincture of belladonna is recommended, and two or three doses of from 5 to 10 drops may be given at intervals of an hour, the mixture being afterwards given alone. If the fever runs very high cold sponging is useful. The joints may be rubbed with opodeldoc (soap and opium liniment) or with a liniment of opium, chloroform, and belladonna. During recovery quinine tonics are of great help. The following may be used:

Quinine, ...	...	16 grains.
Dilute sulphuric acid, ...	...	2½ drachms.
Infusion of calumba,	to make	8 ounces.

Of this a tea-spoonful should be taken in a wine-glassful of water three or four times daily.

Food should be mild and nourishing, milk, light soups, rice, &c., and often change of air is very valuable in getting rid of the lingering affection of the joints.

INFECTIOUS FEVERS WITHOUT RASH (ERUPTION).

Influenza (*Epidemic Catarrh*).—This is an affection similar in its general characters to the disease described as catarrh (p. 154) or common cold-in-the-head. Indeed to cold-in-the-head, when accompanied by sharp fever, pains in the bones, and sickness, the name influenza is often applied. The true influenza is, however, remarkably infectious, which common catarrh never is. In fact influenza is one of the most remarkable of epidemic diseases, capable, as it is, of running through a whole community with marvellous rapidity. Thus one epidemic of it, in 1782, spread over all Europe, missing no country of it, affecting more than half of the people and killing many. Many epidemics of it have occurred since then. The infection is apparently conveyed by the air.

Its **symptoms** resemble those of ordinary catarrh. Its attack is very sudden, and is indicated by chills along the spine, and flushes of heat, high fever, pains in back and limbs, and perhaps sickness. The lining membrane of nostrils, eyelids, mouth, and throat becomes dry, red, and swollen. There are sneezing, intense pain in the forehead and eyeballs, inflammation of the throat and tonsils (p. 136), soreness of throat, harsh croupy cough, and a sense of tightness and pain in the chest. The skin is dry, the tongue white, the bowels confined, and the appetite is lost. The excessive weakness that is rapidly produced is a very marked symptom. In a short time the dryness of the nostrils yields, and a free discharge of watery material comes from them; there is also spit. About the same time the skin becomes more moist, and sweatings occur. Later the discharge from the nose and throat is mattery, and difficulty of breathing and cough are marked. A number of blebs occur on the lips very often. In about three or five days the attack passes off, usually with free sweating, leaving the patient extremely weak and afflicted with troublesome cough. The disease may, however, last several days longer, owing to inflammation attacking the tubes of the lungs and passing downwards, marked by increased difficulty of breathing, hoarseness, cough, and darkening of the face and lips, owing to the affection of the lungs. Bronchitis (p. 270) inflammation of the lungs, that is, pneumonia (p. 274), and other diseases may thus complicate the attack, and delay recovery or cause death. Though death is rare, it is from such complications that it arises.

Treatment.—The patient must be kept in bed in a room kept at a moderate and regular warmth. The kind of food allowed is milk, corn-flour, beef-tea, &c. In case of thirst, barley-water, meal-water, lemonade, soda-water may be given in ordinary quantities. At the very commencement the feet and legs of the patient should be placed in a hot bath containing sufficient mustard to produce a feeling of

tingling, and a hot drink should be administered. The following mixture is useful:

Solution of acetate of ammonia,	2 ounces.
Spirit of nitrous ether, ...	⅔ of an ounce.
Ipecacuanha wine, ...	¼ of an ounce.
Water, ...	to 4 ounces.

Give a large tea-spoonful in water every two hours to grown-up persons, and less to children in proportion to age. For grown-up persons 4 drops of laudanum may be added to each dose, *but not for children.*

If the cough is very troublesome let a kettle be kept boiling on the fire and pouring its steam into the room; and if the throat and chest are sore apply hot poultices of bran or linseed-meal over the throat and upper part of the chest. The bowels should be relieved by seidlitz powders, or citrate of magnesia, or by injection. If the chest is seriously affected, hot poultices all over give great relief, and a cough mixture of ipecacuanha wine and squills (see PRESCRIPTIONS—COUGH MIXTURES) may be given. During recovery, nourishing foods, iron and quinine tonics, &c., are required. Stimulants are often required in the period of extreme weakness. Their use should be regulated by a medical man. If advice cannot be obtained, let 4 teaspoonfuls of whisky or brandy be put into a cup of milk, and let it be given in sips so as to be used up in 12 hours, when a fresh quantity should be made for the next 12 hours.

Hay-fever is described on p. 274.

Whooping-Cough.—This is specially a disease of children, though grown-up people may also be affected with it. Girls suffer more than boys. It is extremely common in children, standing next to scarlet fever as a cause of death. The greatest number of cases occurs in children under eight years of age, and it is more fatal in spring and autumn than at other seasons of the year. It is the most fatal of all diseases to children under one year of age, and three-fourths of all the deaths from it are of children under two years, while only six per cent of the deaths occur above five years. It is, therefore, a disease from which children under five years of age should be most carefully guarded. *It is an infectious disease,* the cause of the disease being given off in the breath of the person suffering from it, and being capable of conveyance by the air and by clothes also. It is specially infectious in the early period of the attack. One attack almost perfectly protects against another. Now taking these two facts together, the terribly fatal character of the disease among young children, and its extremely infectious nature, how great should be the care taken by mothers and nurses to prevent its spread and to protect their children from it. Yet it is the commonest thing possible to find mothers carrying children affected by it in public conveyances, tram-cars, and the like; and very insufficient pains are taken, when it appears in a household, to separate the affected child from the others.

Symptoms.—The earliest symptoms are like those of a common cold, with considerable fever. They begin probably a fortnight after infection has been received. The child is restless and feverish, pale and without appetite. Its breathing is quickened. It sneezes and has an irritable cough. The cough is very troublesome day and night, but specially at night. Fits of coughing come on; a quick short series of coughs ends in a long-drawn whistling breath, followed by another long cough. Some defluxion may be expelled at the end of the fit of coughing, and vomiting often occurs. After a week or a fortnight the fever lessens and the cough begins to be marked by the peculiar whoop, that gives the name to the disease. The cough still comes on in fits or paroxysms, in ordinary cases every hour, in severe cases every half-hour, and in bad cases even oftener. The child knows when it is going to come on by a tickling sensation. It becomes quiet and frightened, rushes to its mother or nurse, rises if it is lying down. The fit begins with a deep in-drawn breath, which is followed by a rapid series of short coughs, becoming weaker, till all air seems driven out of the chest; the face becomes swollen and bluish; the veins are seen full of blood; the eyes are starting, the skin wet with sweat; and the onlooker would believe that the child was choking, when the spasm, preventing the entrance of air into the lungs, begins slowly to yield, and as the air enters the narrowed opening in the windpipe, it produces a long, whistling, or crowing sound, the "whoop," of the disease. Two or three such attacks may occur quickly after one another, till the child is quite exhausted and faint. Often some defluxion is expelled towards the end of the attack, and vomiting is produced. The great strain on the blood-vessels may cause bleeding from the nose or other parts of the air-passages, and the eyes may become blood-shot. The child soon recovers and seems all right till another fit of coughing occurs. This stage lasts from four to six weeks or even longer, though sometimes it

may be only two weeks, and then the spasms become fewer and less severe and defluxion is more free. Health and strength gradually return, but complete recovery may often take many months.

The dangers of whooping-cough are the occurrence of bronchitis, of inflammation of the lungs, and of convulsions. The younger the child the greater is the risk of bronchitis rapidly overspreading both lungs. Without such complications recovery ought to take place, though death may occur during the spasm.

Treatment.—The child should be kept in a room constantly maintained at a moderate degree of heat. The air should be kept moist by steam from a kettle on the fire. The child should be clothed in flannel, and should get light nourishing food in small quantities often. The bowels should be kept regular by castor-oil or syrup of senna. The medicine to be given is bromide of ammonium and belladonna. Children stand large doses of belladonna, and the quantity may, therefore, be steadily increased in the following way: Let a mixture be made containing 64 grains of bromide of ammonium in one ounce of simple syrup (solution of sugar) and three ounces of water. Give a tea-spoonful of this every two or three hours. This is to be continued throughout the first week, and to it occasionally may be added four or five drops of ipecacuanha wine. When the second stage comes on, the same solution of bromide of potassium is to be used, and to each tea-spoonful, as it is about to be given, add one or two drops of tincture of belladonna. If the child stands this quantity well, after one or two days' experience, three drops of the tincture may be added to each dose, and after a further experience of a day or two with the three-drop dose, four drops may be added to each dose, and even five drops. As soon as the black of the eye appears very large no further increase in the quantity of belladonna is to be made. The object of the belladonna is to relieve the spasms of coughing, and as soon as they begin to yield, the quantity of belladonna is to be gradually diminished. To help recovery of strength when the disease is evidently over, nothing is so useful as change of air. This should not be sooner than six weeks after the commencement of the illness. As a tonic to aid recovery, a half to a tea-spoonful dose, according to age, of syrup iodide of iron may be given thrice daily. The infectious nature of the disease must not be forgotten, and disinfection should be practised as described on pp. 395 and 396.

Diphtheria and Croup.—These two diseases will be considered together, since according to many authorities, they are the same disease, which is called diphtheria when it principally attacks the tonsils and parts in their neighbourhood, and is called croup when it principally attacks the top of the windpipe—the larynx (p. 250).

Diphtheria is a contagious disease, the result of the introduction into the body of the person who suffers it of a particular poison. The poison may be harboured on clothes and so carried about. It is thus capable of spreading, of giving rise to an epidemic. In some places it is more or less constantly present, is, that is to say, endemic, probably because of some bad sanitary condition. It occurs in every climate and season. It may attack persons of any age, but is most common between the ages of two and ten years. It seems to have some relationship to scarlet fever, for in many cases diphtheria occurs after scarlet fever.

Symptoms.—The disease begins to show itself within a few days after the poison has been received into the body. But the symptoms may be so ill-defined and vague that the disease is far advanced before the patient really appears seriously ill. The symptoms at the commencement are chills and feverishness, loss of appetite, general weakness and dulness, and marked paleness of skin. Sometimes in the child the first thing that attracts attention is a complaint of soreness of throat. When the throat is examined, already there may be seen the presence of white patches that too surely indicate the nature of the disease. These are patches of false membrane, of a dull white or grey colour, like pieces of wash leather. They are placed on the tonsils and neighbouring parts of the back of the throat. The patches are small to begin with, but they tend to spread and join one another, so that in severe cases the whole back of the throat, including tonsils and uvula (p. 136) is covered with the membrane. If the membrane be scraped it separates in shreds, but grows on again. The throat is also considerably swollen; indeed, even though only one side is attacked, the swelling may be so great as almost quite to block the passage. The glands at the side of the jaw are also swollen. As a result of the swelling there is difficulty of swallowing, though the attempt to swallow does not produce the intense pain common in a severe attack of quinsy (p. 155). In many cases swallowing can be performed all through the illness. The swelling and loss of appetite com-

bined render the patient not inclined to take food, and in children this is a cause of much trouble. For a marked feature of the disease is the excessive prostration it produces. It is to combat this that remedies are, from the first, directed; and so where disinclination to swallow exists, there is great difficulty in getting sufficient food taken to maintain the strength. The disease may not go beyond the stage described, and in ten days or a fortnight recovery begins, the membrane separating in pieces, and being spat out or in young children swallowed. The breath is frequently very foul, because of the decomposition of the false membrane. Even after the throat is quite clear and clean, the patient remains extremely feeble, and in some cases the voice is altered, perhaps lost for a time, owing to paralysis.

But the membrane may extend up into the back of the nostrils and down the gullet towards the stomach, and the disease may be so prolonged that the patient dies of exhaustion.

A most frequent and the most fatal form of the disease is that in which the formation of the false membrane proceeds downwards into the windpipe. The symptoms of this occurrence are those of **croup.** The voice is hoarse, and there is a short dry cough of a peculiar character. It is hoarse and muffled, "like the distant barking of a puppy." Sometimes it is a brassy sound. Accompanying the progress of the disease down the windpipe there is increasing difficulty of breathing. These signs are of the most serious nature, especially so in children, in whom the passage of the windpipe is narrow and easily blocked. As the membrane thickens the voice is lost, and the cough becomes muffled and almost noiseless. Suffocative fits come on, partly due to spasm, partly to the membrane blocking the air-passage, and the patient struggles for breath, the face becoming blue and the eyes staring. One fit passes off, and the patient becomes easier, but speedily another comes on, the person at last sinks into a state of exhaustion and stupor, and death occurs. Usually the end happens before the fourth or fifth day after the symptoms began. Now, sometimes the disease attacks the air-passage only, without any previous attack of the tonsils, no white patches being seen at the back of the throat. In very young children the formation of the membrane in the windpipe may proceed so quickly that death occurs within a few hours of the hoarseness and cough indicating the disease.

The membrane may also pass up into the nostrils from behind, and be evidenced by stopping of the nostrils and discharge of matter and blood.

Further, there are cases of diphtheria in which death occurs within a few days, even in grown-up persons, not from suffocation, but from the violence of the poison and the exhaustion produced. Indeed, death may occur without any apparent formation of membrane, and so rapidly as to leave some doubt regarding the true nature of the disease.

Nor yet is all danger passed when the throat affection has passed away, for death may even then suddenly occur from loss of blood, failure of the heart, and other causes.

Treatment.—The person is to be put to bed in a large well-ventilated room, which must be kept continually at a moderate heat, and in which no draughts must be permitted. A fire must be kept on constantly, and a kettle should always be on the fire pouring its steam into the room. If the least suspicion of the throat being affected is present, the kettle should be a bronchitis kettle (see Plate VIII.—NURSERY APPLIANCES), and the steam should be plentifully poured in the immediate neighbourhood of the bed. If the bowels are confined castor-oil must be given, or an injection. From the beginning every effort should be directed to maintain the strength, sips of warm milk or warm beef-tea, strong mutton-broth, freed from fat and vegetables, eggs beat up in milk, &c., should be administered in small quantities often. Port wine in small quantities is also to be frequently administered. Cold drinks are not to be withheld, and ice may be given to suck. When the patient cannot swallow nourishing injections become necessary. The method of administering them is explained in another part of this work. (Refer to index for INJECTIONS.)

The treatment by medicine is twofold. The throat must be regularly painted several times daily, in the hope of arresting the growth of the false membrane, and a mixture is to be given. The paint is made of equal parts of glycerine and liquor of perchloride of iron—the strong liquor. To each ounce of this one drachm of sulphurous acid is added, and the whole shaken together. A brush is used—camel's hair or goose quill—firmly set on a long handle. The tongue of the patient is held down by a spoon, and the back of the throat thoroughly painted over. The painting must be repeated twice or thrice daily. With children it is difficult to accomplish, and help is necessary. A new method consists in drying the throat as well as

possible and then painting it with Tolu varnish. The following mixture is to be given:—

Chlorate of potash in powder,....	120 grains.
Solution of dialysed iron, ...	½ ounce.
Syrup of orange, ...	1 ounce.
Water, ...	to 4 ounces.

Of this from a half to one tea-spoonful is to be given four or five times daily. When suffocation is threatened steam is to be kept streaming about the bed, and hot cloths may be applied on the neck. A surgeon would probably suggest opening the windpipe by the operation known as tracheotomy (p. 270). During recovery quinine and iron tonics, nourishing foods, cod-liver oil, and, when the patient can bear it, removal to the sea-side, are valuable aids to full restoration of health.

Disinfection (p. 395) must not be forgotten.

Croup, true croup, has been considered in the preceding paragraphs as an extension of diphtheria down into the top of the windpipe—the larynx (p. 250), or into the windpipe itself; or it may be the diphtheria attacks the larynx and windpipe first and directly. There is, however, an ordinary inflammation of the top of the windpipe and windpipe itself not attended by formation of false membrane, to which children, of two and three years old, are specially liable, to which the term croup is also applied.

Its **symptoms** may come on suddenly with alteration of voice, some hoarseness, and frequent dry short cough. The cough speedily takes on special characters, it becomes barking and "brassy." There is fever with difficult and hurried breathing, crowing and piping noise with taking in of breath, quick pulse, and the child is restless and anxious and plucks at its throat. Now it may be impossible to say whether the symptoms are due to the formation of a false membrane in the windpipe, as in diphtheria, or to inflammatory swelling. Death may occur by suffocation or exhaustion, and very speedily.

Croupy symptoms are often present at the commencement of measles.

The **treatment**, in so far as it differs from actual diphtheria, is the same as that described on p. 270 for inflammation of the larynx, and consists principally in the use of hot poultices and cloths over the front of the neck, and the use of steam, hot drinks, &c.

Relapsing Fever (*Famine Fever—Bilious Remittent Fever—Seven-day Fever—Irish Fever*).—This is a fever that seems to be related to periods when extreme poverty prevails, hence its term famine fever. So far as Great Britain is concerned, it came from Ireland, and hence was called Irish fever; but it has also appeared in America, India, Africa, and Russia.

It is undoubtedly due to the presence of a living germ in the blood, is contagious, and may be carried long distances by infected persons and by clothes.

Symptoms.—It is doubtful what period passes after the poison has been introduced into the body before the attack begins, sometimes apparently only a few days, at other times about a fortnight. The attack begins with shivering fits, pain in the forehead, back, and limbs, high fever and great dryness of skin. Appetite is lost; there is thirst; the pulse is very fast; the tongue is covered with a thick white coating, the tip and edges being red. The bowels are confined; there is pain over the stomach, and to the right side over the liver; and vomiting occurs. Jaundice, yellowness of the skin, occasionally appears about the second or third day, hence the idea that the fever is a bilious one. The pains in the joints are of a rheumatic character. Towards the end of the first week there may be delirium. In from five to seven days from the beginning of the attack the fever suddenly passes away, usually after copious sweating, lasting for a few hours, or after free discharge from the bowels. The other symptoms also disappear, but the patient is left weak. For about a week he remains apparently well, and then a second attack suddenly comes on, similar to the first, lasting about three days, and ending like the first. A third attack may follow. Purplish spots may appear during the disease, though there is no regular rash.

Deaths from relapsing fever are not common. Weakness produced by the fever is great, and recovery is slow. The complications apt to occur are affections of the lungs and bowels, looseness, and dysentery.

Treatment.—Light food of milk, corn-flour, beef-tea thickened with rice or corn-flour, is to be given in small quantities. Cold sponging, when the heat is great, with water containing a little vinegar, is refreshing. The patient may have ice to suck, and tea-spoonful doses of the following mixture are to be given every three hours:—

Solution of acetate of ammonia, ...	2 ounces.
Spirit of nitrous ether, ...	¾ of an ounce.
Water,...	to 4 ounces.

To relieve pains and help sleep 5 drops of laudanum may be added to each dose, *but only to*

grown-up persons. The bowels should be moved by castor-oil or by injections. No medicine prevents the relapse. Recovery is to be aided by light nourishing foods, and quinine tonics.

The contagious nature of the disease must be remembered, and the rules for disinfection (p. 396) followed.

Plague (*Pestilence—The Pest—Black Death*).—This is a disease believed to have been observed as early as the second century before Christ. It was common in Egypt, other parts of Africa, and Asia. In the sixth century after Christ it spread over Europe. From that time it continued to exist in Europe, breaking out at intervals in fierce epidemics. Towards the end of the seventeenth century it began to disappear from Europe, from which, however, it had not quite departed till 1841. The last attack in Great Britain was the Great Plague in London of 1665. It seems still to exist in Arabia, Persia, and other parts of Asia. Starvation, filth, and overcrowding are the conditions that favour its spread. It is extremely contagious, being communicated by the breath and carried about by clothing. In many respects it resembles typhus fever.

Symptoms.—The disease appears about five days, on an average, after the poison has been taken into the body. The following are the chief points of the description given of it. It begins with shivering fits or chills, with fever, pain in the forehead, back, and limbs, and great weakness of body. The patient wears a dull, stupefied haggard look. From the second to the fourth day of the disease swellings of glands (buboes) appear at the angles of the jaws, in the armpit and groins. The eyes are red, skin hot, tongue as if covered with wool, or dry, black, and cracked. The gland swellings cause pain, and come to matter if the patient does not die before. In some cases boils or carbuncles appear on the limbs generally, and purple spots (*petechiæ*) are not uncommon. Sickness and vomiting of bilious matter and perhaps bloody matter are frequent.

Death within twenty-four hours of the beginning of the attack is frequent, and the majority of deaths occur within four or five days. The death-rate is not less than one in three.

Treatment is similar to that of typhus fever. No treatment that can cut short the disease is known. Disinfection and avoidance of the conditions of the spreading of the disease, uncleanliness, overcrowding, &c., are the means to prevent its extension.

Yellow Fever (*Black Vomit—Yellow Jack*) is a disease of hot climates, common in the West Indian Islands. It has been introduced into Europe, but does not tend to spread except in times of great heat. Cold kills it. It attacks Havana almost yearly between the months of April and December. It is rarely absent from the West Indies, and is most fatal from May to August. It is a contagious disease, and its contagion can be carried by clothing, and conveyed by infected ships. A person who has suffered from one attack is safe from a second.

The **symptoms** may appear within one or two days after the poison has entered the person's body, or may not occur for six or ten. The attack is sudden, beginning with shivering, fever, dry skin, intense headache, pain in the back and limbs. The eyes are glistening, bloodshot and red; the face is congested; there are great thirst, loss of appetite, tenderness over the stomach, sickness and vomiting. The tip and edges of the tongue are very bright red, the rest being covered with a white coat. The lips and throat are also bright red. The pulse is at first very fast, but may greatly diminish in speed, even while the fever remains high. The fever may not remain high for more than a day or two, but the vomiting and tenderness over the stomach continue. At first the vomit is of the contents of the stomach, then it becomes coloured with bile, and later has a "coffee-grounds" appearance, the black vomit, due to mixture of altered blood. The motions are often black for the same reason. By the second or third day of the disease the whites of the eyes may be seen to be yellowish, and the yellowness spreads to the face and over the body, the jaundice being well marked. The urine, which is at first clear and of the usual quantity, becomes, with the advance of the disease, of a deep yellow from the presence in it of bile. The colour may deepen to orange red, and at the height of the attack almost no urine may be made. In favourable cases the quantity becomes large and the colour becomes very dark. Death may take place within a few hours of the attack from the violence of the poison, the person becoming collapsed. It may occur at any time in the progress of the disease, the fifth day being regarded as critical. In cases that have gone on for several days death is usually due to bleeding from the stomach or bowels or kidneys, or from exhaustion of the heart. Where recovery takes place it is gradual, and the jaundice takes long to disappear. The death-rate is very high.

Treatment.—The patient should be confined

to bed and all exertion strictly forbidden. The room should be large and well-aired, but kept constantly at a moderate warmth. The bowels should be relieved by injections. Corn-flour, beef-tea, chicken broth, milk, and similar food should be given at regular and short intervals. Large draughts of lemonade and barley-water are to be allowed. Ice is to be sucked to allay sickness, and for the same purpose mustard poultices are applied over the stomach. In cases of recovery the person must not be allowed to sit up till fourteen days have passed.

It is needless here to mention any of the many drugs tried for the disease. All discharges from the patient must be at once disinfected, as recommended on p. 396, and removed, and other steps taken to limit the disease (see p. 396).

Hydrophobia (*Dog-Madness—Rabies*).—The word hydrophobia is derived from two Greek words, *hudōr*, water, and *phobos*, fear, the dread of swallowing and the spasms produced by the attempt being a marked feature of the disease. It is a disease to which dogs, cats, wolves, and foxes are liable. It is due to a particular poison, which seems specially to exist in the saliva or spit of the animal affected by the disease. It can only be produced in human beings by the direct introduction of this material into the body by a bite or other wound. A person may be bitten by a dog and may in consequence be seized with the disease, although the dog did not at the time show signs of the disease. Cases have been due to a dog, not known to be suffering from the disease, licking the hand of its master on which some slight wound was present. The bite of a cat may produce it. Probably, however, not more than a third of the persons bitten by mad dogs take hydrophobia, even when no attempt has been made to destroy any poison that may have been imparted from the dog's mouth. When the bite has been through clothes the risk is less than if the part of the body had been uncovered. More men suffer from the disease than women. There seems no doubt that a bite from a healthy dog cannot produce the disease. A dog must be suffering from the poison, whether it is evident or not, before it can impart the disease to another.

Symptoms.—It is very doubtful how long the poison requires to reside in the body before the disease appears. The shortest interval between the bite and symptoms has been about twelve days. The interval is seldom less than a month, and is on an average six or seven weeks. In some cases many months have passed before the disease appeared, and some have been recorded in which the interval extended to years. The appearance of the disease after four months is, however, seldom. The wound by which the poison gained admission to the body usually heals as easily as an ordinary wound. It is said that among the first symptoms in many cases is return of pain to the place of bite, hot tingling pain, shooting from the part. Such is often not present. Other symptoms are restlessness, shivering, uneasiness, a feeling of illness, disturbed sleep, lowness of spirits, and discomfort about the throat with some difficulty in swallowing liquids in particular, while at the same time there is thirst. As the disease advances the patient becomes excited, the eyes look wild, and he wears an expression of terror, and is liable to outbreaks of delirious excitement in which he may strive to injure himself or others. The chief symptom is the spasm that occurs on attempting to drink. At first it is mere difficulty of swallowing, but soon the attempt causes a spasm, a "catch in the breath," which, in the course of a few hours, becomes marked as a strong contraction of the muscles of breathing, there being a strong effort as in taking in a deep breath, so that the shoulders are raised and the corners of the mouth drawn outwards. The spit cannot be swallowed. It collects in considerable amount, and hangs thickly from the mouth, a source of great annoyance to the patient. Even when the patient is quite conscious, the impossibility of swallowing is marked. The person may take a glass of water, and, making up his mind with great effort, may carry it quickly to his mouth with agitation, but the spasm comes on and the glass is violently thrown away, and any water that may have got into the mouth is violently thrown out, while the patient shudders, and marked spasms of the muscles for breathing occur. The very thought of drinking is terrifying. The mere sound of running water produces spasm, and the state of terror and agitation is extreme. In advanced cases any sudden noise, or a rush of cold air, will bring on a convulsive attack. As the disease advances the patient becomes feeble, the voice hoarse, and the convulsions more frequent and severe. Death occurs from exhaustion or from suffocation in convulsion. The disease is without exception fatal, death occurring in from two to six days.

In dogs the symptoms of rabies are sullenness, fidgetiness, and continual shifting of position. The dog seems to see things in the air, which he

gazes at, follows, and snaps at. His appetite is perverted. He swallows bits of coal, wood, &c. Saliva streams from his mouth, and hangs in sticky strings from it, disturbing him and causing constant efforts with paws to get rid of it. He makes a hawking noise in the effort to clear the throat and mouth. His bark is hoarse, and eyes bright. There is evidently intense thirst, and *the dog has no fear of water, for he often buries his muzzle in water at the height of the attack;* but he cannot drink owing to paralysis of muscles, or spasmodic irregular movements of them. He bites anything that comes in his way, and may thus in a short time infect other dogs, cats, and other animals. Finally the dog reels and staggers, his hind legs and lower jaw lose their power, and he dies in convulsions or from exhaustion.

It is to be noticed that nervous people, who have been bitten, may by mere mental anxiety work up symptoms resembling those of hydrophobia. This false hydrophobia may be known from the presence of anxiety alone and not delirium, from the spasm on drinking being a mere difficulty of swallowing, which can be overcome, and being overcome, does not return. In such cases if the patient's mind be set at rest, and some soothing medicine given, a 30-grain dose of bromide of potassium, for example, the symptoms disappear.

Treatment.—Whenever a person is bitten by a suspicious animal the circulation of blood ought at once to be stopped, for a brief period, in the bitten part by tying a tight band, if it be a limb, above the bitten part, and carefully washing the bite and allowing it to bleed freely. As soon as possible—immediately, if possible—the part should be burned. A hot iron, poker, &c., may be freely and deeply used, or nitric acid painted lightly over the place with a brush, and then wiped off with a sponge and cold water. Attempts to treat the disease have failed. Attempts may be made with chloral hydrate, in from 10 to 30 grain doses, to keep down the spasms. The patient should be kept very quiet in a dark still room. Persons in attendance ought to be careful, since a bite from a patient, or the spit of the patient cast on the attendant, may impart the disease.

Glanders and Farcy are diseases of the horse and of animals of the same species. They may be communicated to man by poison contained in the discharge from the nostrils of the diseased animals. It is, however, rare in man.

Symptoms appear from three to eight days after the introduction of the poison, and in some cases after a longer interval. They are high fever, great heat of skin, shiverings, quick pulse, pains in muscles and joints of a rheumatic character, headache, sleeplessness, profuse sour sweatings and clamminess of skin. The nostrils become congested, and a biting watery fluid comes from them, which soon becomes thick, and mattery. A rash, at first of red spots, like flea-bites, appears scattered over the face, limbs, neck, and belly. They become pimples like peas, grow yellow, and soon burst, pouring out matter, and leaving bad ulcers. The eyes yield matter; sores form in the mouth and throat, and the lungs become affected. Lumps, turning into boils, form in the skin on the face and in the neighbourhood of joints. The patient becomes very weak; delirium comes on, followed by stupor and death. The disease runs its course in sixteen days, on an average, but some cases end fatally in a week. It is usually fatal.

In glanders the nose and ear-passages are early affected. In farcy the poison is introduced in a wound on the body or limbs. The part becomes red and inflamed, glands in the neighbourhood become affected, and lumps (farcy-buds) and boils form in the skin. Both are, however, practically the same disease.

Treatment.—No curative treatment is known. The patient's strength must be maintained, as well as possible, by nourishing food and stimulants, and the affected parts should be carefully and regularly cleansed, abscesses opened and cleaned out, &c. A person attending a case ought to wear india-rubber gloves while bathing the affected parts.

Syphilis (vulgarly called *Pox*) is a contagious disease, is, indeed, a type of that class of diseases capable of being contracted only by the direct introduction of a special poison into the body of a person. The poison is, in this case, communicated directly by sexual intercourse or indirectly by inheritance. To this rule there are, however, exceptions which must be noticed, and will be stated in the course of the description of the disease. How the disease first originated, where, that is to say, the first poison came from, it is as impossible to state as to declare where the first poison of small-pox came from, or, for that matter, the first seed of corn or wheat or potatoes. When and in what place the disease first manifested itself it is equally impossible to decide. It appears, however, to have occurred in Europe, and certain parts of Asia, from the earliest times. It has spread

over the entire globe, by means of the commerce between countries, though there are yet some regions free from it. The disease is not affected by climate. During the latter part of the fifteenth century the disease assumed an epidemic form, and spread throughout the whole of Europe.

One attack of syphilis protects against a second, but then the disease does not run its course in the brief period occupied by other fevers, such as small-pox, scarlet fever, &c. Its progress occupies months, even years, and sometimes continues throughout the life of the person who has contracted it.

Symptoms.—The fearful character of this disease will be best understood by an account of the progress of an ordinary case, to arrest which no steps have been taken.

The first occurrence of the disease is the appearance of a sore, called the **hard chancre,** at the place where the poison has been introduced, usually some part of the genital organs. This sore, however, does not appear for a considerable time after the poison has been received. There is a period, that is to say, corresponding to the period of incubation or hatching of ordinary fevers, which has been referred to on p. 397. This interval is on an average four weeks. It may be only a little over two weeks, while, on the other hand, it may extend to nearly six weeks. During this interval there is nothing whatever to lead the person, who has exposed himself to the disease, to suspect the possibility of its existence. A person, whose conduct has rendered his infection only too probable, after failing to discover anything for a week or two, may conclude that he has (undeservedly) escaped, but this conclusion is not justified so early as this. The form which the sore takes on its first appearance is that of a small red dark-coloured pimple, which slowly grows larger. The person may be, and often is, unaware of its presence, since it is not painful nor itching. In a few days the pimple is broken by the separation of a part of the surface, and speedily a little ulcer is formed. The ulcer is of a peculiar character. It is not deep but shallow, and all round the sore is a firm ridge of a dark red appearance. If the part be taken between finger and thumb it has a hard feeling, as if a little mass of gristle had been deeply imbedded in the substance of the skin. The ulcerated surface is greyish, and rather dry, only a scanty thin discharge being produced by it. In about six weeks it reaches its complete formation, when it is about the size of a split pea, and it thereafter begins to diminish. When it is healed it leaves a white scar that will never disappear. The scar is below the level of the surrounding parts, which are somewhat hardened, and of a darker colour than is usual. So little trouble does this sore occasion, that the person may from first to last be ignorant of its existence. The sore is single; several of them do not occur on the same person. While this is the usual form and course of the sore, it may appear as a mere scratch or crack, healing easily and leaving scarcely any recognizable scar. What has been described is the true, hard chancre, the first result of the activity of the special poison of syphilis. But there is another sore, called soft chancre, or **chancroid,** also the result of the introduction of a poison, obtained in the same way as the preceding, but which never gives rise to syphilis. It is described elsewhere (see INDEX). It is painful, pours out abundant discharge, is accompanied by inflammation and swelling, but has not the hard gristle-like feeling of the true chancre. Moreover, matter from the soft sore, getting into a scratch on any other part *of the same person's body,* will reproduce a similar sore; while, on the other hand, matter from the true chancre cannot produce a second sore on the same person, though it can produce a sore like that it came from on another person. One or two weeks after the appearance of the *true* chancre, the glands in the groin become affected. In fig. 113 on page 208 is a representation of the glands in the groin. Those marked *d. e. f.* in the figure receive material from the genital organs, and if the poison of syphilis has been there introduced, it in time reaches the glands and affects them. They increase in size, not necessarily all of them, but several. The increase is slow and painless. On pressing with the finger, they are felt to be hard and are freely movable in their positions. They may become as large as almond shells, and so they remain for years, not coming to matter and giving rise to no trouble, but presenting almost conclusive evidence of the existence of syphilis. This is another distinguishing feature between hard and soft chancre, for the poison from a soft sore reaches the same glands, but causes in them inflammation and formation of matter, so that one or more buboes, as they are called, are produced, that is, abscesses, which are extremely stubborn and slow to heal.

And now there follow evidences that the poison has not only passed up from the spot, where it was introduced, into lymphatic glands, but has gained entrance to the blood, and

has affected the constitution. These evidences are called the **secondary symptoms** of syphilis, or briefly **secondaries.** The first of these is the appearance of a rash on the skin, which comes out in from six weeks to three months after infection, usually in about sixty or seventy days. The rash is at first of rosy red spots, which appear about the chest and belly, and may cover the whole body like a crop of measles. They soon become dull red or brown, and finally disappear, to be succeeded by pimples, which have a coppery colour. The pimples by and by fade, leaving copper-coloured stains in the skin, which take some time to disappear, but leave no scar. They begin on the trunk of the body, but spread to the arms and legs, and, unlike many ordinary skin affections, do not miss the palms of the hands and soles of the feet. They may come out in crops, off and on, for several months. Moreover, this rash of syphilis is capable of assuming many various forms; but, whatever the form, one great peculiarity is the coppery colour of the staining of the skin which attends it. The skin of the scalp is often affected, scales forming; and the hair loses its gloss, becomes dry, and tends to fall out, so that baldness may be produced.

Some amount of feverishness, loss of appetite, paleness, weakness, headache, and rheumatic like pains, often very severe, are not uncommonly experienced just before the appearance of the rash.

On page 307 it is explained that mucous membranes, the covering of red parts like the lips, inside of the mouth, throat, &c., are practically of the same structure as the skin. Hence it is not surprising that affections of the mucous membranes occur similar to those of the skin. The mouth and throat commonly suffer; the tonsils (p. 136) are liable to ulcerate, the nostrils and box of the windpipe sharing in the trouble. Raised patches about the corners of the mouth and anus (p. 130) are frequent.

Now it is certain that the matter that oozes from, or covers, these ulcers and raised patches, is capable of communicating the disease. This is a fact of the utmost importance to observe. What it implies is this, that a person who has such syphilitic ulcers or patches in throat or mouth, or tongue, is capable of communicating the disease by a kiss, if the slightest crack or fissure exists on the lip of the person kissed, by which the poison could enter. Moreover, for the same reason, a healthy person using without cleansing, cups, tumblers, &c., that have been just previously used by a syphilitic person may contract the disease. Thus while at the beginning of these paragraphs on syphilis it has been said that the disease is usually contracted by impure sexual intercourse, it is not uncommon to find it, in perfectly innocent persons, acquired by such other ways as have been indicated. For example, a hard chancre on the lip is often seen. A child who has inherited syphilis from its parents may communicate it to its wet nurse during suckling, and a wet nurse by the same means may communicate it to a child. Besides the affections of skin and mucous membranes, mentioned as secondary symptoms of the disease, others are common. Serious inflammations of the eye—inflammation of the iris and of the retina and optic nerve (p. 375)—are quite ordinary results. Affections of bones and joints, indicated by severe pains of a rheumatic character, usually worse at night, are also frequent. The bone affections are commonly marked by the appearance of small painful lumps, usually on the shin-bones, to which the term "nodes" is applied. In fact the diseases which may arise in the progress of the secondary stages of syphilis, due to the poison in the blood, are innumerable, and are only properly treated when their cause is recognized. This secondary stage lasts for from six to eighteen months, during which the general health of the patient is liable to serious disturbance and depression. At the end of that time the disease may disappear, even without treatment, and not again trouble the patient. Symptoms are, however, apt to show themselves now and again still indicative of the operation of the poison, such as the occurrence of skin diseases of various kinds, of ulcers, &c., which are obstinate, even refusing readily to yield to treatment.

Moreover, at a variable interval after the end of the secondary stage, what are called **tertiary symptoms** may reveal themselves. The chief evidence of the third stage is the formation of collections of inflammatory material in various parts of the body, in skin, mucous membranes, muscle, bone, liver, and other internal organs, brain, and spinal cord. These new growths are called **gummata.** These growths readily ulcerate and break down, causing destruction of the substance of the part in which they happen to be. They may disappear without ulceration, but still their disappearance is attended by destruction of the part in which they are lodged and consequent contraction of the part, shown by deep and permanent scars. In the skin the growths form flat elevated patches of a deep purplish-red colour, called

syphilitic tubercles. Such destructive growths may form in the gullet, leading to contraction and difficulty of swallowing, in the box of the windpipe, attacking the vocal cords (p. 262) and causing hoarseness and loss of voice, in the nostrils, producing destruction of the gristly parts, giving rise to offensive discharge (STINK-NOSE, p. 365), and ending in falling in of the bridge of the nose; and in many other parts may similar growths occur. Tumours may form in the brain, and may cause deafness, blindness, paralysis, and other symptoms dependent upon their position. Intense and persistent headaches continuing for weeks without intermission are extremely suspicious of syphilitic disease of the brain.

The consequence of such long-continued disease is a gradual but marked loss of general health and vigour, shown by sallowness of complexion and increasing thinness and loss of strength, so that the result of the disease is a miserable existence and a premature end.

Inherited Syphilis. A husband may, of course, infect his wife. Syphilis is a very common cause of abortion, occurring usually about the fifth or sixth month of pregnancy. One miscarriage after another may thus be occasioned, each succeeding one may be at a later period than the one before, till after several abortions a child is born alive. A child may be born with, already at birth, signs of the disease. It is shrivelled, puny, and unhealthy looking, and speedily dies. Commonly, however, at birth the child is healthy looking, and the signs of the disease do not appear till three or four weeks later. A syphilitic child has sores, chaps, and cracks at the corners of the mouth, ulcers of the mouth, and is afflicted with snuffles, owing to similar affections of the nostrils. Little soft growths are found about its anus (p. 130), and a rosy rash about the buttocks and neighbouring parts is a most common sign. It is peevish and fretful; its skin is dry and withered-looking, its face old and weird-looking, its hair scanty, its body thin and wasted. These symptoms, if the child live, disappear about the end of the first year, but scars are left to mark the seat of the sores. In later life the bridge of the nose is sunken, the teeth have a pegged appearance, and the clear part of the eye (cornea) is liable to suffer from an inflammation that makes it cloudy and of a ground-glass appearance.

A child may inherit syphilis from either parent; but a curious fact is that the child of a syphilitic father may exhibit the disease which the mother has escaped. The father may, that is to say, infect the child without previous infection of the mother.

Treatment.—It may be stated as a general rule that, if proper treatment be adopted early in the disease and persisted in, and *if the patient be a person of temperate habits, and, above all things, if he abstain from habits of drinking*, the disease may be got rid of within two years of infection. In regard to children it may also be said that, provided the disease does not appear for several weeks after birth, *and if the child be properly fed and in every way well cared* for, proper treatment will effect a cure.

The general treatment consists in good nourishing food, moderate exercise, moderation in, indeed abstinence from, all liquors, perfect cleanliness, and moderate exercise in the open air. Frequent washing of the whole body with soap and water, and an occasional Turkish bath are of importance. Flannel should be worn next the skin, and care to avoid chills taken. The patient should continue his work or business to give mental occupation. Smoking should be entirely given up if the mouth or throat is ulcerated, otherwise it should always be moderate.

As regards special treatment, a brief statement may be given of the treatment of an ordinary case in its different stages; but wherever possible the patient should place himself in the hands of a qualified physician, and should scrupulously follow his every direction. As regards the chancre, it is doubtful whether any treatment by burning, &c., will destroy the risk of the constitutional disease arising. The sore readily heals if cleanliness and frequent bathing are practised. If the patient is anxious to have it destroyed, caustic should not be used, but strong nitric acid. A brush, moistened with the acid, is lightly brushed over only the crack or ulcer, sound skin being avoided, and the sore is then bathed with cold water. A healthy sore remains, when the slough, due to the burning, separates. It soon heals if kept clean by bathing. Often the secondary symptoms appear before the patient is aware of having contracted the disease, the chancre having been unnoticed. When they appear, or to avoid them, if the chancre has been observed, the drug employed is mercury. Mercury has gained a bad reputation, because in former times it was improperly used. When properly used it is perfectly safe, and it is the only drug that can satisfactorily deal with the disease. When required when the secondary symptoms are slight, or used as a precaution, it may be given

in pill according to the following prescriptions:—

Blue Pill, 1 grain.
Extract of Gentian, 1 grain

to be made into one pill. One such pill is to be taken after meals thrice daily. It is well, before taking the first pill, to clear out the bowels by a double strong seidlitz-powder. If the mouth and gums become sore the pill is to be taken less frequently—twice daily, for example—or its use may be stopped for a day or two and then resumed after another purge. If treatment is not begun till the secondary symptoms have lasted for a time, such as sore throat, skin eruption, &c., the following mixture may be employed instead of the pills:—

Bichloride of Mercury, ...2 grains.
Chlorate of Potash, ...60 ,,
Water,..............................to 8 ounces.

Of the mixture a dessert-spoonful in water is taken thrice daily after meals.

If the above treatment by pills is adopted as a precaution only, it should not be stopped after several weeks because no symptoms have appeared. It should be continued for at least six months, and preferably twelve months, though not necessarily continuously. It may be stopped for a few days at a time and then resumed, and if after four or six months no symptoms have appeared, the dose may be reduced to two pills daily. Where the secondary symptoms have appeared the treatment *must not be dropped* simply because the rash on the skin has disappeared, the throat become well, and the health has apparently been restored. It ought to be persisted in for twelve months, and beyond that if symptoms still exist. If symptoms have ceased long before the twelve months have passed, the medicine may be stopped for short intervals and then resumed, and smaller or less frequent doses employed. Six months must pass, during which the person is free of symptoms, before the person can be pronounced cured.

In the third stage of the disease the drug used is iodide of potassium in 3-grain doses, dissolved in water and taken twice daily. It is well, in ordinary cases, after ceasing the use of mercury to use the iodide for several weeks. Iodide of potassium has a marked effect in the nervous troubles of the third stage. Thus for the continuous intense headache a dose of 10 grains may be given to begin with three times a day. The dose is daily increased by 3 or 4 grains till the person may be taking even 90 grains a-day, or till the headache ceases, when the dose is gradually brought down; but the smaller dose is to be persisted in for months. Sarsaparilla in dessert-spoonful doses may be given with the iodide. It helps the patient to bear the latter drug.

Great benefit is derived from a course of treatment at sulphur baths, such as Aix-la-Chapelle.

There are some people who cannot bear either mercury or the iodide, but it is impossible here to consider exceptional cases.

Ulcers and other sores may be bathed with a wash containing, to each ounce of water, 2 grains of sulphate of zinc.

For children a flannel bandage should be made to fit round the belly. On the surface next the skin a piece of mild blue ointment of the size of a pea should be smeared nightly. The movement of the flannel rubs it into the skin, which should be washed every third day. By the mouth syrup iodide of iron, a third of a teaspoonful, should be given thrice daily. Cleanliness and good milk are essential.

The extremely contagious nature of the disease has been pointed out. It is, therefore, scarcely necessary to say that a syphilitic person should abstain from sexual intercourse, from all contact, indeed, with others. It is probable, however, that in the third stage the contagiousness is not marked.

As regards marriage, it is almost a crime for a syphilitic person to marry before a year has elapsed without any sign of the disease. A person who has passed through the disease, and has been properly treated, should, therefore, not marry till three years have passed from the time of infection.

Cerebro-spinal Fever (*The Black Sickness* (popular name in Dublin)—*Spotted Fever*).—This is a fever which is probably contagious, and certainly occurs in an epidemic form. It is rare after forty years of age, and is not uncommon among young children. The symptoms are due to inflammation of the membranes of the brain (p. 91) and spinal marrow.

Symptoms.—The disease may begin with feverishness, headache, pains in the back and limbs, and feelings of illness lasting for a few hours or a couple of days before any serious disease is feared. Usually, however, the attack is sudden, coming on with collapse and insensibility or with severe shiverings (rigors), intense headache and dizziness, excessive pain in the back of the neck and along the spine, constant vomiting, pain in the stomach and cramping

of the muscles of the legs. The fever is not necessarily great, but the patient is restless and delirious or drowsy. The skin is over-sensitive, so that slight touches give rise to complaints of pain. One marked symptom is a stiffening of the muscles of the head and back, so that the patient's head and neck are arched back. A rash of blebs (*herpes*) appears on the lips. Purple spots (*petechiæ*) come out about the second day, in severe cases within the first twenty-four hours. They appear first on the legs. Purple blotches also appear over the body in very severe cases. Death may occur from collapse within a few hours of the attack, or from the first to the seventh day, the patient passing into stupor and from it to death. Death may not occur for several weeks, and may then be due to complications. Paralysis is a common complication and so also are affections of eyes, ears, and joints.

Even in favourable cases the illness lasts from two to six weeks, the extreme weakness that results being a cause of the delay.

Treatment.—If the attack begins with collapse, it must at first be met with the application of heat to the limbs and over the heart, and the administration of small quantities of stimulants. Mustard plasters over the chest and back are also recommended. When this stage is over, the intense pains in the head and back are relieved by ice bags on the back of the head and along the spine. For the same purpose opium given every two or three hours in 25-drop doses, as long as it appears safe, is recommended. *This must only be given to adults. Opium must never be given to children without express medical orders.* To them bromide of potassium in 5-grain doses every two hours may be advised.

Small quantities of strong beef-tea, and similar fluid nourishment, are to be given frequently.

At a later stage of the disease 3-grain doses of iodide of potassium may be given every four hours to aid in the removal of the inflammatory material poured out on the brain. To children the dose should begin at 1 grain.

The disease is extremely fatal, often within the first twenty-four hours owing to the nervous disturbance. Energetic treatment at the outset might relieve the brain, and therefore no delay should be permitted to occur in seeking skilled advice, wherever possible.

NON-INFECTIOUS FEVERS.

Ague (*Intermittent Fever—Marsh Fever—Malaria*).—Ague or intermittent fever is not a disease that may be communicated from one person to another. It is, nevertheless, a fever which is apparently due to the introduction of some poisonous agent into the body. The poison, called **malaria**, is bred in marshy places, where the energies of the soil are not used up owing to want of cultivation. Two conditions are apparently necessary for making a tract of land malarious: one is that for a season the land must be soaked with water which has no regular and sufficient outlet; and the second is that, following the period of soaking, a period of drying occurs, during which, under the influence of a hot sun, the land becomes dried up for some distance below the surface. It is during the latter period that the poison of malaria is produced, and that the region becomes unhealthy. Thus ague-districts are more common in countries where periods of drought regularly follow rainy seasons.

Drainage and cultivation are certain methods of ridding a district of malarious characters. In regions where ague and similar marsh fevers are common the poison rises from the ground with the vapours given off from the ground. In consequence, the poison is more abundant in the atmosphere nearer the ground, and is in diminished quantity in proportion to the height above the ground. So marked is this, that in ague-districts the upper stories of houses are more healthy than the ground-floors. The poisonous vapours may, however, be carried by air-currents up the sides of mountains in the immediate neighbourhood of the ague-districts, and by the same means may be conveyed to some distance beyond the place where they have been produced. The intervention of a considerable surface of water, such as that of a lake or river, will greatly prevent such conveyance; and a thick belt of trees has a similar effect.

One attack of ague, instead of protecting against a second, renders a person more liable to renewed attacks from the least exposure to the poison. Moreover, one who has suffered from ague is liable to other attacks even without being again exposed to the action of malaria.

Fever may appear in persons within a day or two after the reception of the poison, while others may have been removed for months from the malarious district before evidence of their having become affected by the poison presents itself.

Symptoms.—The feature that marks marsh fevers is that there are several attacks of fever separated from one another by intervals, during which the sufferer appears comparatively well. In its progress the fever has three well-marked

stages: the cold stage, the hot stage, and the sweating stage, following which is the period of the intermission, as it is called, in which the fever is completely absent. This period lasts for a variable time, and is succeeded by a second attack of the fever, going through the same stages as the first, ending in an intermission, followed by another attack, and so on. In one case the interval between the beginning of the first attack and the beginning of the second is only twenty-four hours. There is, in this case, a renewed attack of fever daily. This form is called **quotidian ague.** In another form, from the commencement of the first attack to that of the second is forty-eight hours. That is to say, there is a renewal of the fever every other day. This is called **tertian ague.** In a third form, the fever is renewed the third day from the beginning of the previous attack. This is **quartan ague.** In other cases the fever returns every fourth, fifth, or sixth day.

For some time before the disease actually attacks, the person may complain of weariedness, loss of appetite, headache, and pain in the back, or the disease may begin suddenly.

The *cold stage* is marked by a feeling of coldness; the person shivers; his teeth chatter and his limbs tremble violently; the face and hands are blue with the cold; and the skin is shrivelled and presents the appearance of "goose-skin." There is uneasiness about the stomach; headache and pains in back and limbs are present. Much very clear water is passed, and frequently. This stage may last from half an hour to several hours. The cold is only apparent, for if the temperature be taken with the thermometer (p. 10) it will be found already above the usual height.

The *hot stage* comes on gradually with the disappearance of the pinched and blue appearance of the skin. From feeling comfortably warm the patient becomes intensely hot, the face being flushed, skin dry and harsh, pulse full and frequent, and thirst being great. The person becomes restless, and sometimes slightly delirious. The headache is severe; and the sickness continues. This stage lasts from one to four or five hours, or even longer.

The *sweating stage* begins with the appearance of beads of perspiration on the face and brow. The hands and skin begin to get moist, and the person feels more comfortable. Soon copious sweating breaks out all over the body. The fever falls and the pulse becomes slower and softer. The breathing is less hurried than in the hot stage. Soon the fever is quite gone, and the patient comparatively well, but tired and inclined to sleep. The average length of the whole attack is from five to six hours, but it may be prolonged for double that time. In some cases one or other of the stages may not be well marked.

After a varying time a second attack comes on, as already noted, which goes through a similar course.

There is no definite time when the whole illness will pass away. But a person who has suffered from ague is always liable to renewed attacks on the slight provocation of a cold, indigestion, &c.

Persons who continue to reside in a malarious district, and who suffer from periodical attacks, gradually pass into a chronic state of ill-health, marked by a peculiar sallowness of complexion. Serious changes occur in the blood, liver, and spleen, producing a condition of poverty of blood and a tendency to dropsy, jaundice, and various other affections.

Treatment.—The treatment of ague is naturally twofold: that of the attack and that of the intermission. During the attack little can be done except in the way of making the patient as comfortable as possible. From the nature of the disease it is needless to attempt to arrest its progress. During the cold stage, therefore, the use of a plentiful supply of warm coverings, hot drinks, hot-water bottles, &c., will be grateful to the patient; and so, on the other hand, will be light coverings, a cool atmosphere, and tepid sponging of the body during the hot stage. It is during the period of absence of fever between two attacks that medicine must be administered to ward off, if possible, a new attack. The medicine to be given is quinine. Ten grains should be dissolved in water, to which a drop or two of tincture of steel have been added to aid the solution, and this dose given at the end of the sweating stage. It is to be repeated in four or six hours. After each renewed attack the quinine is to be administered in this way, and after the fever has ceased to return, the use of a daily dose of quinine must still be persisted in for a week or more. Nourishing foods should be administered, and to aid in the restoration of strength 30 drops of Easton's syrup (syrup of quinine, iron and strychnine) should be given in water thrice daily before food.

Whenever possible a person attacked by ague should be at once removed from the marshy district.

The prevention of ague is best accomplished by efficient draining and cultivation of the

district where it occurs by the clearing of jungle, and by similar means. The exercise of great care may enable one, compelled to live in a malarious district, to evade the disease. The person should sleep in the upper part of the house, should avoid going out late in the afternoon and early in the morning; all water should be filtered or boiled before use; excessive fatigue should be avoided; and quinine should be regularly taken.

Whenever a person, from repeated attacks of the fever, has become constitutionally affected, nothing should be allowed to prevent removal from the malarial situation to a healthy climate for a prolonged period.

Remittent Fever (*Bilious Remittent—Jungle Fever*) is a form of ague, but more severe in its symptoms and of a much more fatal tendency. It is due to the same cause as ague, and presents similar symptoms.

Symptoms.—The disease has its cold, its hot, and its sweating stage like ague. The cold stage is, however, very short, and hardly recognizable. The fever of the hot stage is very high, and this period is prolonged, lasting from six to twelve hours. The vomiting which occurs is violent and distressing. The material vomited up is first colourless, then bilious and sometimes bloody. The sweating stage is not so marked as in ague. With it the fever diminishes and the other symptoms improve, and the *remission* occurs, which differs from the interval of ague in the important fact that the disease does not disappear for a time as in ague, but simply abates to renew its violence in a short time—from ten to twelve hours. The remission usually occurs in the morning, and the fever is at its height at midnight. Day after day the attacks recur, usually at first with increasing severity. The illness lasts from five to fourteen days, and a favourable termination may be expected when the remissions are distinct and last for several hours.

Treatment is similar to that of ague. It is said to be well to begin with a purgative as soon as the disease manifests itself, and to an ordinarily strong adult 3 to 5 grains of calomel, the same of compound extract of colocynth and of powder of scammony, with 5 grains of quinine are advised. In the absence of these separate ingredients, one blue and one compound colocynth pill with 5 grains of quinine form about the same dose. No more medicine is to be given till the first remission, when 10-grain doses of quinine must be administered as advised for ague. If the person cannot retain the quinine on the stomach it should be carefully injected into the bowel (see ENEMA). To relieve the sickness, small pieces of ice should be given to suck, and warm cloths are applied over the stomach. When the fever remits, nourishing food is necessary, and if the exhaustion is great stimulants in repeated very small quantities. The other directions given under Ague apply equally to Remittent Fever.

Rheumatic Fever (*Acute Rheumatism*).—Acute rheumatism is a disease accompanied by very high fever, and attended by characteristic joint pains. The tendency to the disease runs markedly in families; and previous attacks increase the liability of a return. It affects mostly persons under the age of thirty. Exposure to colds, chills after overheating, &c., are frequent causes.

Symptoms.—The disease usually appears with signs of an ordinary attack of cold, such as a general feeling of illness, loss of appetite, sore throat, disturbed sleep, pains in the bones, feverishness, &c., the signs of what is commonly called an influenza cold, symptoms described under catarrh (p. 154). The chief signs of the fully formed disease are, high fever, pains in the joints, and severe sweats. The joints attacked are usually the larger ones, ankles, knees, wrists, shoulders, and elbows. The joints are not attacked all at once, but one after another as a rule, one joint getting well when another is becoming more painful. The pain is often excessive, so that the person lies straight and motionless in bed, afraid even of the slightest shake to the bed. The affected joints are hot, tinged with redness, tender to touch, and swollen. When the swelling has fallen, and the pain nearly gone, a feeling of stiffness remains. The muscles are also affected, and liable to painful twitchings. After the pain has begun in a joint, it increases till it is very severe, and then gradually dies away, the swelling disappearing with it. However much the joint may be swollen, matter is practically never formed in it. During the illness the whole body is bathed in sweat, which has a peculiar sour smell, easily perceived by everyone who comes near the patient. The sweats continue throughout the disease, and gradually pass off with recovery. The fever is often so high as itself to threaten life. In addition to these symptoms the tongue is white, appetite bad, bowels irregular, and pulse fast (120 per minute).

While these are the usual signs of a regular

attack, the disease may occur in a much milder form, with slight fever lasting only a day or two, only one or two joints being affected. In many such cases the disease frequently returns.

The length of the illness is never very definite, varying from two to six weeks or longer, but when the patient is properly attended to the severe symptoms should not last much beyond nine days. Recovery of strength is, however, slow. Death from the rheumatism itself is not common. But in the train of rheumatism are a great many other diseases, especially heart disease (namely, valve disease of the heart (p. 239), and inflammation of the pericardium (p. 238)), inflammation of the lungs and air tubes, and various others. Indeed the great risk is that of affection of the heart.

Treatment.—The patient should be in an open bed lying between blankets. The affected joints should be kept at rest. An aid to this is obtained by wrapping them in cotton wool, secured by a flannel bandage. The principal medicine now given is salicine or salicylate of soda. It is administered in 20-grain doses in water every two hours for twelve hours or so, when the pains are generally relieved and the fever falls. Thereafter the powders are repeated every three or four hours or at longer intervals. The evil of the remedy is that it frequently produces deafness and unpleasant noises in the ears, and sometimes sickness and faintness. In spite of the noises in the ears, &c., the powders should be persisted in if necessary, as the unpleasant symptoms attending their use will pass away in a few days. But if sickness or faintness arise a more sparing use of them must be made. It is marvellous how quickly in many cases this treatment relieves. When it does so, the dose should be continued twice or thrice daily for several days after the fever has passed away. Then a quinine and iron tonic should be given, and great care must be taken for some time to prevent a relapse. Sometimes this treatment fails. In such a case the old treatment with potash must be resorted to. Thirty grains of acetate of potash are to be given every 3 or 4 hours. At bed-time 10 grains (*to an adult*) of Dover's powder will relieve pain and help sleep. Quinine and iron tonics are also necessary after the fever has passed. Throughout the illness nourishing, easily digested foods are to be given *in small quantities* frequently repeated. Milk and milk puddings, thin mutton broth, &c., are best, but no butcher meat should be allowed till recovery has taken place. Soda water and milk is a grateful drink to the patient. The bowels also require attention, an ordinary purgative medicine being given as required.

Though the treatment has thus been mentioned in some detail, it is needful to say that no case ought to be without medical supervision, unless that is absolutely unavoidable. A physician will often detect commencing affection of the heart, and take steps to prevent it if possible. Neglected cases too often end fatally in time because this evil has not been guarded against.

Chronic Rheumatism, as it affects the joints, is discussed on p. 33.

Section XIV.—SOME GENERAL DISEASES.

TUBERCULOSIS AND SCROFULA. GOUT. CANCER. DROPSY.

TUBERCULOSIS AND SCROFULA.

Tuberculosis is the term applied to a general disease, due to the formation of tubercles in various organs of the body. The nature of tubercles has been shortly explained on p. 165, and at greater length on p. 278, but to give a complete idea of the disease, the chief points of these explanations may be again mentioned. A **tubercle** is a little nodule, grey in colour, about the size of a millet seed, consisting of a collection of round cells. It is to be considered as a new growth, foreign to the part in which it is present. The little nodule tends to increase in size by the growth of others round it. By its growth it destroys the substance of the part in which it is placed, occasioning also inflammation in the surrounding parts. It has no great vitality, and undergoes changes, which begin in the centre of the nodule, the result of which is to convert the firm grey mass into yellow cheesy material. The process may go on till the nodule becomes quite broken down into soft matter, and, if the matter can break out from the part, an ulcer is left. Instead of softening, the nodule may become hard by the

deposit of lime salts in it, and become converted into a little solid mass in the substance of the tissue where it is lodged.

Now the effects produced by the formation of such tubercles depend on the organ or tissue of the body in which the diseased process is going on. In the general disease tuberculosis the formation of the grey nodules proceeds in most of the organs of the body—lungs, liver, kidneys, lymphatic glands, bowels, membranes of the brain, &c., and the symptoms produced are those of a fever, and strongly resemble symptoms of typhoid fever. This form of the disease may last two or three weeks, and its termination is death. The true nature of the disease it is extremely difficult to recognize during life.

On the other hand the formation of tubercles may be limited to one organ of the body, at least at first. Thus if the formation is principally in the lungs, it produces consumption (p. 277). In the bowels it produces consumption of the bowels (p. 105). The same process going on in the membranes of the brain is the cause of acute water-in-the-head (p. 101); and a similar tubercular deposit in lymphatic glands is believed to be the cause of the swelling and breaking down of the glands that are the main features of scrofula.

Recent investigations have tended to establish a relationship between the growth of tubercle and the activity of some peculiar form of germ. That tubercle spreads by contagion is evident. In cases of tuberculous consumption the throat is commonly affected by tubercular ulceration, so that the voice is hoarse and may be lost; and this is due to the contact of the spit from the lungs. Moreover, in such cases tubercular ulcers are usually found in the bowels, probably because the contagious matter is swallowed and the ulceration thereby extended. But definite experiments have conclusively proved the truth of the contagious character of the disease (refer to p. 393).

The tendency to tubercle is hereditary. No age is free from the possibility of an attack; but it is most common in early life.

It is needless to discuss the symptoms or treatment of the general disease, and the special affections of lungs, bowels, and brain have been considered elsewhere. Where the tendency to this form of disease is known to exist in families, much may be done to avoid its appearance. The general treatment is the same as that suggested for scrofula, which, as has been already indicated, is a manifestation of the tubercular taint.

Scrofula (*Struma—King's Evil*) is a constitutional condition in which the general health is much weakened, and in which there is a great tendency to slow inflammation of various parts of the body and to the formation of abscesses and ulcers slow to heal. (The disease was called King's Evil from the idea that it could be cured by the king's touch.) It is a condition occurring in families and descending from parents to children. The organs of the body specially apt to suffer are the lymphatic glands, which become enlarged, softened, and readily break down, becoming converted into cheesy material. When it is the glands about the neck (p. 208) that are specially affected, the disease is evident, but other glands deep-seated and not within reach of examination are equally prone to the affection, which may, therefore, not be so evident. Scrofulous persons are often in early life of a pasty complexion, pale and flabby, with sluggish circulation, stunted in growth, with short narrow chest, and prominent belly, and soft muscles. Others again are of bright fair complexion, with light red hair, and are unusually bright and clever. Many children, though apparently scrofulous, gradually grow out of this condition and become vigorous men and women.

While inflammation and formation of matter in the glands are the popularly known signs of the scrofulous condition, many other organs of the body may be the seat of scrofulous disease. Thus some kinds of inflammation of the eyes are essentially scrofulous; scrofulous diseases of bone and joints are common; chronic eruptions and ulcers of the skin, discharges from the ear and nose, are also frequently the result of the bad condition of health. Consumption of the lungs or bowels may arise from the same general weakness.

Scrofula is believed to be a manifestation of tubercle, discussed above, and the breaking down and suppuration of glands, the distinctive feature of scrofula, to be the result of the deposit within the glands of tuberculous matter.

Treatment.—Nothing so much aids in the progress of a scrofulous tendency than bad food, bad air, want of cleanliness, and the absence of opportunities of healthy exercise, and nothing is so effective in removing the disposition to the disease than the removal of these evils. A scrofulous child should be regularly bathed; it should be clothed in flannel. Plenty of fresh air and sunlight are absolutely necessary. Nothing is, consequently, so valuable as a change from a close town to the sea-coast. Moderate sea-bathing is very useful. If this cannot be ob-

tained, the child should be bathed at home daily in a bath containing Tidman's sea-salt, and should be vigorously rubbed afterwards. Food is to be liberally allowed, especially sweet milk, eggs, soups, &c. Cod-liver oil is the chief medicine, and should be given for a long period, indeed long after health appears quite re-established. Most children learn to like it. Small doses should be given at first, half a tea-spoonful twice daily, and the dose should be gradually increased till a dessert-spoonful or a table-spoonful is being taken thrice daily. To those who, after patient trial, cannot get over the taste of the oil, malt extract or malt extract and cod-liver oil may be given. Another valuable medicine is iron, given as dialysed iron (4 to 10 drops (according to age) five times daily in water), or as syrup iodide of iron (a half to one tea-spoonful thrice daily), or as Parrish's syrup of the phosphates, commonly called chemical food, given in a half to one or two tea-spoonfuls thrice a day. The cod-liver oil and the iron tonic may be given at the same time.

Glands that have become swollen and painful ought not to be rubbed, nor irritated in any way (see p. 209). The oil and the syrup of iodide of iron ought to be persevered with, and the neck simply protected by a strip of flannel. Frequently the affected glands will recover under this treatment if not worried into suppuration. If, however, matter forms in the glands, the sooner a surgeon opens them the better.

GOUT.

Gout is a markedly hereditary disease, descending from parents to children in a very remarkable way. Men are more frequently attacked than women; the age most liable to the disease is between thirty and forty-five. The circumstances that usually determine an attack in those liable by inheritance to the disease, or that excite the disease for the first time, are habitual excess in eating, specially in the over-eating of animal food and rich dishes, long-continued excess in drinking, especially strong wines, such as port, sherry, madeira, and malt liquors (beer and porter), and prolonged want of proper exercise. It appears also that persons subject in their occupation to the influence of lead are rendered more liable to an attack, if other circumstances favour it. It appears that the disease is due to an excess in the blood of a substance called uric acid, either because it is formed in the body in too large quantity, or because it is not removed from the blood by the kidneys in the urine as it ought to be. It is a disease specially apt to return frequently, very slight causes being sufficient to determine an attack in those subject to it. Thus even a slight degree of indigestion, irregularity of bowels, cold, mental anxiety or worry or excitement may occasion a fit of the gout in gouty persons.

Symptoms.—An acute attack of gout usually comes on suddenly during the night with pain and swelling in a joint, commonly the joint that forms the ball of the great toe. The joint becomes not only much swollen, but also turns red and shiny, the veins on the foot and part of the leg being very marked. The pain is often extremely severe, and is burning or shooting in character. Other joints may also be attacked, the smaller ones specially. The least movement is almost unbearable, and even the weight of the bed-clothes is not endurable. Towards morning the pain lessens, but next evening it returns, and this may continue for a week or ten days, when the severe symptoms pass away, though the joint remains swollen and tender for some time longer. However swollen the joint may be, matter does not form. Attending the joint affection there are general symptoms of disturbed health, shiverings and sweatings, loss of appetite, white tongue, increased heat of skin, quick pulse, confined bowels, and scanty high-coloured urine, from which a brick-red deposit separates out on cooling. The sleep is much disturbed; cramps and startings of the muscles of the leg are common; and the patient is of very irritable temper. After the first attack the joint apparently quite recovers. As a rule the disease returns sooner or later, generally within a year; and not only does it tend to return, but the intervals between each "fit" become shorter. With the greater frequency of attack, more joints are liable to suffer—joints of foot, hand, ankle, knee, &c. As the disease becomes chronic the joints become permanently altered. They enlarge, and deformities are produced, due largely to the deposit within the tissues of the joint of masses of urate of soda, called "chalk-stones," which not only form prominences and irregularities, but by being deposited around the joint tend to fix it in unusual and awkward positions. Abscesses may form round the chalk-stones, from which they may be discharged, leaving ulcers. The general system tends to become affected and the person to grow feeble and weak.

Those who suffer from attacks of gout are often warned of an on-coming "fit" by symptoms not well marked, but which, by experience, they know too well the meaning of. Those

symptoms may be connected with the digestive organs—flatulence, heartburn, irregularity of bowels, or connected with the heart, such as palpitation; or there may be headache, irritable temper, and various other nervous symptoms.

There are forms of **irregular gout** that show themselves by severe stomach disturbance, such as acute spasmodic pain or cramp and bilious vomiting, or by disturbance of the heart, evidenced by palpitation, faintness, &c. By similar attacks of irregular gout the breathing may be much disturbed and rendered so laborious that suffocation seems to threaten. Nervous and other symptoms may also be due to a similar cause.

Treatment.—Very strict regulation of the habits of life is one of the most important elements in the treatment of gout. The person must exercise great restraint in eating, and must take no more than is necessary for proper nourishment. A mixed animal and vegetable diet is the best, but the amount of animal food in particular must not be in excess. Of this class of food the best kinds are white fish, game, fowl, and mutton. Fat meat such as pork, salted and spiced meats, and all rich dishes are to be avoided. In regard to vegetables, some believe in the free use of celery. Stewed fruits are allowed, but no pastries, and the fruits should be sparingly sweetened. Extreme moderation in drink is absolutely necessary, beer, porter, and rich wines, champagne included, being rigidly abstained from. Such wines as hock, moselle, claret, alone are safe; whether they should be used at all, and, still more, whether any whisky or brandy may be taken, ought to be left to the decision of a medical attendant. Water should be the principal drink. Tea and coffee are not necessarily harmful. Potash, soda, and lithia water, may do much good, and ought to be taken freely, but only between meals.

The gouty person should take regular outdoor exercise daily, and should go early to bed and rise early. The clothing should be warm. Baths are of great use, and specially a well-ordered Turkish bath. Exposure is to be avoided; and sudden changes of temperature are to be guarded against. For this reason, where a choice can be made, an equable climate is to be preferred. As regards treatment during an acute attack, it should be begun with opening medicine, such as rhubarb (10 grains) and bicarbonate of soda (15 grains), the dose being repeated as found necessary. To relieve the pain the drug most extensively used is meadow-saffron or colchicum. The preparation used is the wine, given in water in 10 to 30 drop doses every four or six hours along with 6-grain doses of citrate or carbonate of lithia or potash. The use of the colchicum may be continued for several days if it agrees with the patient. At the same time the action of the skin and kidneys is to be promoted by the patient being kept warm, and drinking freely of barley-water, soda-water, or cream-of-tartar water flavoured with lemons. The food should be light and nourishing—milk and bread, a little beef-tea, &c.—and rather spare in quantity. The affected joint should be kept at rest, supported in a raised position, and surrounded by a piece of flannel dipped in warm water, and covered by cotton wool.

In chronic cases 3 to 6 grains of carbonate of lithia should be taken twice daily in a wine-glassful of water, and Carlsbad or Vichy water largely used.

CANCER.

Cancer (Latin *cancer*, a crab—*Carcinoma*).—The name of this disease is derived from the appearance of the part attacked by the disease, as it struck the ancients, the veins surrounding the diseased part resembling a crab's claw.

Cancer is considered in this section more as a matter of convenience. It is still a question much discussed whether cancer ought to be counted a local or a constitutional disease, and many reasons can be adduced for answering the question either way. It is certain, however, that after cancer has appeared in any part, however small and limited its position may be, and however insignificant it may appear, it will in time spread along various channels and affect the whole system.

Nature.—Its character is that of a tumour, swelling, growth, or deposit, which tends to spread, not simply by becoming larger and squeezing aside the healthy substance of the part in which it is placed to make room for itself, but by growing into the healthy parts, invading them, and incorporating them into itself. It can never, therefore, be removed from its position as a whole without other parts being disturbed, but if removed the whole mass of tissue in which it is placed must be cut out with it. Moreover, even if removed, it tends sooner or later to return, perhaps just because it so invades the tissues that it is impossible to make sure that all of it has been removed. This feature of it is one of the chief reasons why it is called "malignant." For it is evident that a tumour, whose tendency is always to return to the attack, is likely some day to overcome its

victim. A "simple" tumour, however, is one which, once removed, is done with. Not only does cancer tend to spread by direct invasion of the substance of the part where it is placed, but it also tends to spread to distant parts by conveyance along vessels. Blood-vessels are doubtless channels along which particles of cancerous material may be carried to parts at some distance from the original growth, and which, taking root in the new situation, proceed to grow and form a secondary tumour. Other channels, which afford an even readier means of transit, are the lymphatic vessels, which, as has been noted on page 200, are found in every tissue of the body as drains for the removal of excessive nourishment supplied to the part, and also for the removal of waste products. Into these channels, therefore, juice and particles from the tumour will find their way. The lymphatic vessels pass to lymphatic glands in order that the material they carry may be worked up into a fit state for return to the blood. Thus it is that some time after a cancerous tumour has appeared in some part of the body the glands in the neighbourhood are almost certain to be found enlarged and otherwise affected. It is this that renders it so difficult to remove a cancerous growth with any certainty of permanent cure. For the cancerous material may have been carried considerable distances from the original tumour by such channels, without any signs of the transference being evident for a long time. It is this also that renders it imperative that a cancerous growth should be remorselessly cut out as soon as it is discovered, and the smaller and more insignificant the growth appears the more eager should the patient be for its removal. But it is just at this stage of its growth that patients are indisposed to permit an operation. It is so small, or it gives so little perhaps no trouble, what is the need of operating at present? Wait till it is bigger, painful, troublesome, then the patient will consent. It is necessary earnestly to insist on the undoubted fact, the reasons for which have just been given, that it is while the growth is small and trifling that its removal is most hopeful, and that waiting till it is bigger means practically waiting till it is hopeless.

As to the nature of the growth itself, cancer is essentially formed of a degenerate kind of cell, and is originally connected with structures mainly of the epithelial type (see p. 16). Thus the surface layer of the skin consists of epithelial cells (p. 307), the mucous membrane of the mouth has a similar superficial layer (p. 136); the stomach and whole length of the intestinal canal (p. 140) has an outermost layer of cells; the membrane covering the windpipe and tubes of the lungs, as well as the air spaces of the lungs themselves, are covered with epithelial cells (p. 252); the kidney and bladder have similar inner coatings (pp. 290, 293), while glands, the salivary glands (p. 137), the glands of the stomach and intestine (p. 139), are also lined with epithelial cells. Now it is in these situations and others of a similar character that cancer is found, the cells coming under some degenerative influence, which causes them to multiply in enormous numbers and thus to invade the surrounding tissues and form deposits. The cells are held together by a small amount of connective tissue (p. 16), in whose spaces the cells lie. A cancer tumour is thus a growth formed of masses of cells in groups held together by connective tissue, the cells being originally derived from the natural cells of the part.

Varieties of cancer depend mainly upon the relative proportions of the cells and binding tissue, and of a fluid—the cancer juice—also present in the growth. Thus **hard cancer** or **scirrhus** has the binding tissue in greatest abundance, and forms a very hard tumour; **soft cancer, encephaloid** or **medullary cancer** contains more cells and is of a very soft consistence, growing also with greater rapidity than the hard variety; while **epithelioma,** or skin cancer, consists mainly of flat cells like those of the skin, or cells similar to those of glands, and occurs in the shape of an irregular ulcer.

Seat.—The position of the tumour may vary as already indicated. It may occur on the skin or on mucous membranes, like that of the tongue, lips, stomach, and other parts of the alimentary canal, in the bladder and womb, in glands, such as the salivary glands and breast, the glands of the intestinal tract, the liver, the testicle, the lungs, the eye, bone, lymphatic glands, nose, and many other parts. In fact it may occur almost anywhere. For even though it may originate only in epithelial structures, as already noted, it is easily transmitted to other parts, in which it could not begin, by the channels of the blood-vessels and lymphatics. In men a common seat of cancer is the lip, where it is of the epithelioma variety. In women the breast and womb are frequent situations, hard cancer being most frequently in the breast. Internally the stomach, liver, and lungs are common situations.

The **causes** of cancer it is not easy definitely

to state. Undoubtedly hereditary influence is great in many cases. Age has something to do with liability to the disease. The greater proportion of cases in men occur between fifty-five and sixty years of age, and in women between forty-five and fifty-five. It is twice as common in women as in men; and the liability seems to be greater in women who have borne children. These are of the nature of predisposing causes (see p. 4). Sometimes the occurrence of the growth seems to be determined in position by the presence of some long-continued irritation. Thus the irritation of a short juicy pipe, constantly smoked, has determined the appearance on the lip, and the irritation of a ragged tooth on the tongue, while cancer of the breast in a woman has followed at no distant time a blow on the breast. Frequently, of course, no such local cause can be suggested. It may be that with a constitutional tendency to the disease, it only required such an irritation to determine its occurrence.

The **progress** of the disease is slow or rapid according to the variety of the growth and its site, soft cancer being rapid in growth, epithelioma very slow. In its course the tumour continues growing for a certain time, and then it begins to break down, an irregular ulcer being formed from which a fœtid discharge proceeds. In time, sooner or later as the disease spreads quickly or slowly, and according to the speed with which it extends to other organs, the health suffers, and a constitutional state arises to which the term "cancerous cachexia" has been applied. The countenance is peculiarly pale and sallow, and the sufferer wears a very anxious and careworn look. The general surface of the body acquires a yellowish hue, the appetite is diminished, the strength gradually fails, and the pulse is weak. The patient complains of lassitude and of inability for exertion. Emaciation sets in, at last death ensues from exhaustion, or the combined effects of discharge, debility, and pain. Life may, however, be shortened more speedily owing to the interference of the tumour with the functions of some important organ, or to frequent attacks of bleeding from the ulcerating surface, caused by the disease opening into blood-vessels.

Symptoms of cancer it is impossible to discuss in detail. Those of cancer of the breast and the womb will be considered in the section on DISEASES OF WOMEN. As regards internal cancer, its presence requires for detection a skilful and experienced physician. Concerning cancer of the lip and tongue it is only necessary to say that the presence of a ragged ulcer, with hard base, from which a foul discharge proceeds, and which refuses to heal, is suspicious, and ought to cause the sufferer to seek early and skilled advice.

Treatment.—No drug will cure cancer. The virtues of one medicine after another have been lauded in vain. Time and more experience have shown the worthlessness of them all. The only treatment for cancer is removal, if that is possible. Caustics have been used to burn out the mass, and are occasionally used still, but removal by the knife is the preferable operation. This a surgeon will not undertake unless with a prospect of being able to remove the whole growth. It must, therefore, be done early, before the disease has invaded lymphatic glands and other organs. When it is too late to operate, the only treatment is one to relieve the symptoms, to support the strength of the patient and to alleviate pain. Each case must, however, be treated on its merits, and requires medical supervision.

DROPSY.

Dropsy is an accumulation of fluid which has oozed out from the blood-vessels in the minute spaces in the tissue, or in some of the cavities of the body, the cavity of the belly for example. It is called by other names according to the position of the accumulated fluid. Dropsy confined to the tissue under the skin, in the foot, leg, or arm, for example, is called **œdema** or **anasarca**. Dropsy of the belly is **ascites** (p. 191). The accumulation of fluid round the lung in pleurisy (p. 266) is a dropsy, and a similar collection round the heart is called **hydropericardium** or dropsy of the heart (p. 238). On p. 203 it is explained that fluid is constantly oozing from the finest blood-vessels into the tissues to nourish them, that more fluid oozes than is necessary, and that the excess is picked up mainly by lymphatic vessels, and afterwards returned to the blood. Now suppose more fluid escapes than can be picked up by the lymphatics, or suppose the absorbing vessels are somehow prevented fulfilling their purpose, the excess of fluid will remain and accumulate in the tissues, and in a short time that part will be the seat of dropsy.

Causes of dropsy are thus readily understood. The quality of the blood may be so altered that fluid passes out very readily and in great excess. This happens in anæmia (p. 234), and in Bright's disease of the kidney (p. 295).

Again where obstruction exists to the return of blood to the heart, the blood accumulates in the veins; there is greater pressure on the blood, causing more to pass out of the vessels, and preventing also its absorption, and so dropsy again results. This obstruction may be merely local. A tumour pressing upon the main vein of a limb will thus produce dropsy limited to that limb. In pregnant women the pressure of the enlarging womb on the veins frequently causes swelling of the legs. Dropsy may be more general. Thus in certain diseases of the liver the circulation is obstructed, and since all the blood from the belly and the lower limbs passes through the liver the obstruction is experienced in all these parts and dropsy of both legs and of the cavity of the belly will soon ensue. A more general cause even than this, and more common, is heart disease, where the onward movement of the blood is hindered by some valve affection (p. 239) causing accumulation of blood in the veins of lungs, liver, and other parts, and occasioning extensive dropsy. In such cases the parts at the greatest distance from the heart, and in the lowest situations, will feel the pressure of blood most, and will show the evidence of dropsical swelling soonest and most markedly, for example the feet and legs. The same condition may be produced even when no real affection of the valves exists, if the heart is so feeble that it does not contract with sufficient vigour to cause a steady and regular circulation of the blood. The walls of the heart, yielding too much to the pressure of blood within them, may stretch unduly, and thus the heart becomes dilated and thin-walled in proportion to the degree of stretching. Under these circumstances the circulation is sluggish, and in time the blood in the veins experiences a backward pressure, which causes an undue amount of fluid to pass out into the tissues, and dropsy ensues. In these circumstances the swelling appears first in the feet and legs. It must not, however, be thought that swelling of the feet and legs is in every case caused by something wrong with the heart. Many people are troubled with swelling of the feet and lower parts of the legs after standing long or going about a good deal, the swelling usually disappearing after a rest in bed. This does not necessarily imply any particular disease. When a person stands, the weight of the column of blood in the veins of the legs is considerable, and if the vessels be relaxed in any degree the vessels widen unduly, and the movement of blood is slower than usual, allowing a greater oozing of fluid than can be quickly removed.

In pleurisy, dropsy of the heart, and similar instances, the accumulation of fluid is due not to obstruction to the return of fluid, but to an active determination of a much greater than ordinary quantity of blood by the acute inflammation going on.

The **treatment** of dropsy depends on the cause. The cause should if possible be removed; the state of the liver should be corrected if possible, the weak heart strengthened, &c. Drugs are employed for the purpose of removing from the blood and casting out of the body a larger amount of water than usual, and so encouraging the picking up of the dropsical fluid into the current of the circulation. Active purgatives, which cause large evacuations of watery stools, do this, such as jalap and elaterium. Other drugs effect the same thing by promoting an increased flow of urine, such as nitre, gin, spirits of juniper, and digitalis. Profuse sweating by means of hot-air baths aids in a similar way. Digitalis is a very useful drug, since it both strengthens the heart and promotes the action of the kidney. It is in cases where the dropsy is due to some condition of the heart that digitalis proves most valuable. By its strengthening action on the heart it causes more vigorous contractions and tends to restore efficiency to the circulation. But the employment of these means is always attended with risk, unless used by those who really understand the cause of the dropsy and adapt the remedy with care to the circumstances of the case. Therefore the treatment needs determination by a physician.

When treatment by drugs fails the accumulated fluid is frequently drained off by tapping.

THE MANAGEMENT OF CHILDREN IN HEALTH.

HIGH MORTALITY OF CHILDREN.

That there is need for spreading broadcast fuller knowledge than the public evidently at present possesses of the proper methods of dealing with children, both in health and in illness, is strikingly evident from the statistics carefully collected and detailed by the late Dr. Wm. Farr, of the Registrar-General's Office. The facts are so clearly given in Dr. Farr's own words in his annual reports that a few extracts will best show what they are.

"In England and Wales the deaths of 2,374,379 infants in the first year of age were registered in the 26 years 1838–63; and of the number 1,329,287 were boys, 1,045,092 were girls."

"Nearly 100,000 infants die annually, in the proportion of about 56 boys to 44 girls."

"Even in the healthy districts of the country, out of 1,000,000 born, 175,410 children die in the first five years of life; but in Liverpool district, which serves to represent the most unfavourable sanitary conditions, out of the same number born, 460,370, *nearly half the number born,* die in the five years following their birth."

That is to say, one in every six children born dies within the first five years of life, even in the healthy parts of the country, but in the unhealthy parts the proportion is one-half. Moreover, Dr. Farr showed that the majority of the deaths occurred *within the first year of life.* Thus "of 100 children born, 15 die in the first year, 5 in the second, 3 in the third year, 2 in the fourth, and 1 in the fifth; making 26 in the 5 years of age. Of the 15 who die in the first year, 5 die in the first month of life, 2 in the second, and 1 in the third."

Now what is the cause, or what are the causes of such a tremendous infant mortality? That question also Dr. Farr tries to answer. The

result is given in tabular form. In the three years 1873–75 the annual number of deaths, from all causes, of children under one year of age to every 1000 births was 278. The separate causes of these 278 are given in the table:—

Total number of deaths to every 1000 births,		278
Of which the number of deaths caused		
by premature birth and atrophy (wasting) was		70
,, lung diseases	,,	51
,, convulsions	,,	31
,, diarrhœa (looseness of bowels)	,,	24
,, tubercular disease	,,	21
,, whooping-cough	,,	12
,, teething	,,	6
,, measles	,,	4
,, scarlet fever	,,	3
		222

The causes of the remainder are not detailed.

Of the 278, no less than 125 were due to such diseases as atrophy (wasting), convulsions, and diarrhœa. Commenting on the table Dr. Farr says: "Some of the principal causes are improper and insufficient food, bad management, use of opiates, neglect, early marriages, and debility of mothers; but whatever may be the special agencies at work which are so prejudicial to infant life, it must be borne in mind that a high death-rate is in a great measure also due to bad sanitary arrangements." "*The causes of death which are more directly the result of neglect and mismanagement are convulsions, diarrhœa, and atrophy*," and again, "the causes most fatal to infant life in factory towns, and which are inseparable from bad nursing and feeding, are diarrhœa, convulsions, and atrophy."

It is to be observed that in this table the number of victims of measles and scarlet fever is small, but it is in the second, third, and fourth years of life that these diseases are worst, and not during the first year to which the table is limited. It seems that since 1875 a considerable decrease has taken place in the average English death-rate, a decrease affecting not only the adult portion of the population, but the infant portion as well. It seems plain that this improved state of affairs is due to the operation of acts of parliament referring to public health, to the greater care consequently taken to keep down and rectify, as far as possible, unhealthy conditions, to more vigorous measures in dealing with and preventing the spread of infectious diseases, and to other similar causes. But public health acts touch very little those great causes of infant mortality, noted by Farr, "neglect and mismanagement," which are still the chief causes of an unnecessarily high rate of infant death. These causes are not limited to particular classes of society, though they may be more strikingly evident in one class than in another. Mismanagement of children is certainly very common in every grade of society, and is as frequent a cause of childish ailments in the houses of the rich as in those of the poor. The first part of this section is, therefore, devoted to a consideration of the proper methods of managing children in health.

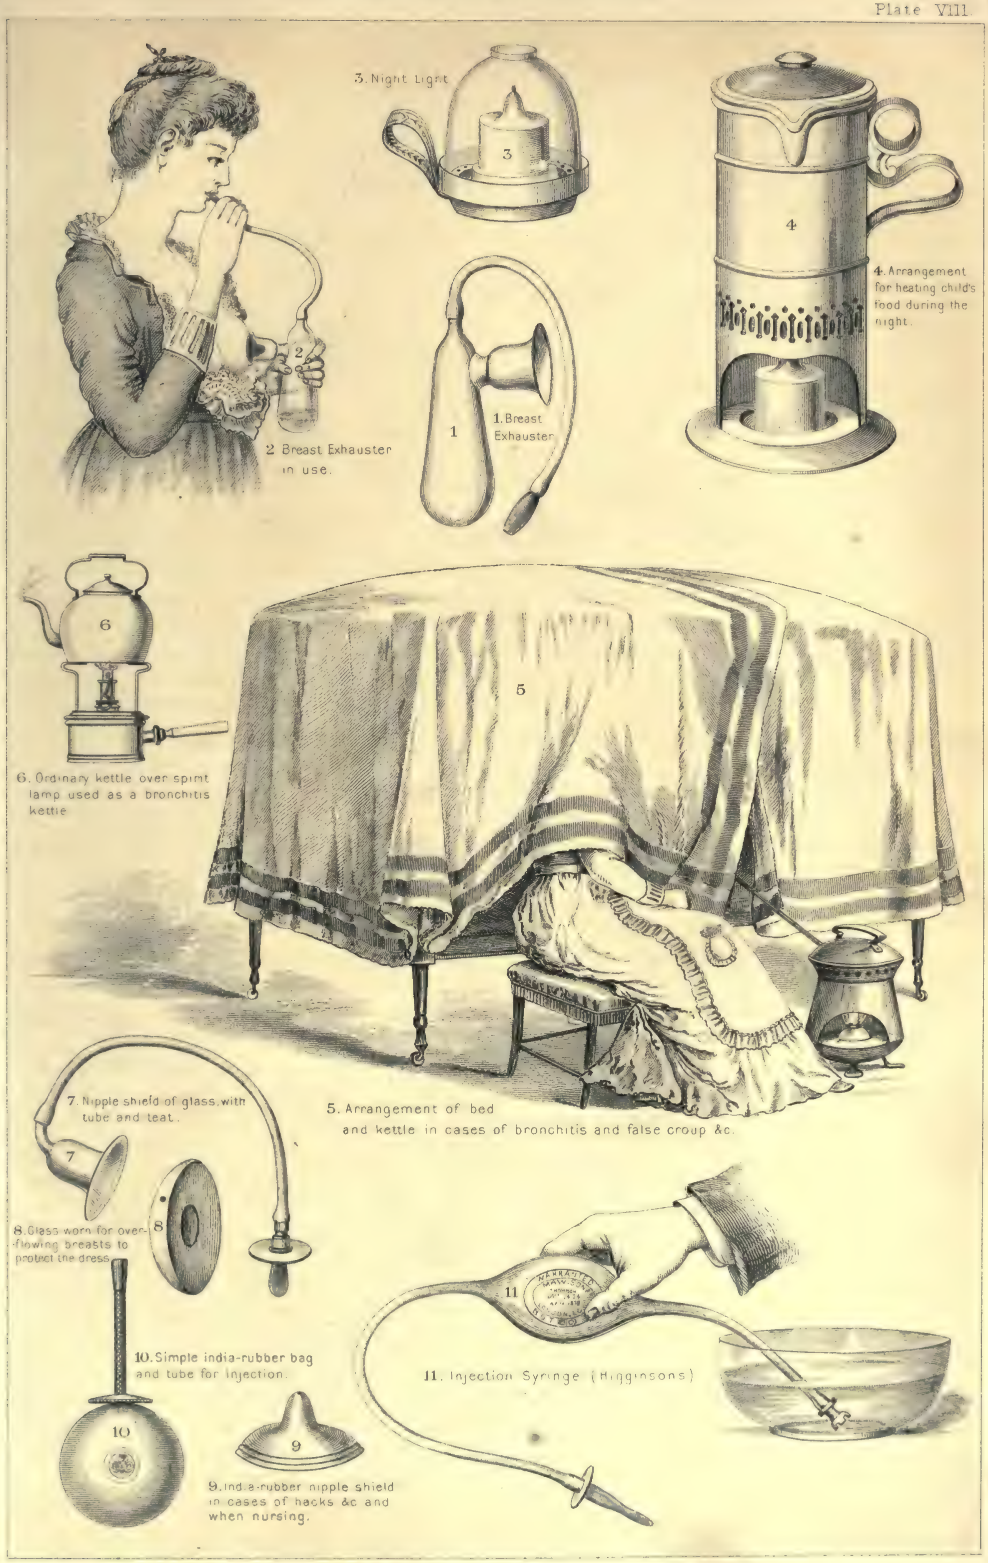
THE MANAGEMENT OF THE NEWLY-BORN CHILD.

Food.—From the day of its birth till it is four or six months of age the child should be nourished, in ordinary circumstances, *entirely* by its mother's milk, and during that period no other food of any kind whatever ought to be allowed. It is a mother's chief duty in relation to her child to suckle it, and neither her pleasure nor convenience should, for a moment, be allowed to come into consideration. A bad state of the mother's health may make it advisable, not for her own sake only but also for her child's, that the child should be otherwise reared, but this is the only valid reason as a rule.

It often happens that there is no milk in the mother's breasts for some hours after the birth of the child, and it is the custom of most nurses in the meantime to feed it with spoonfuls of sweetened water. This is entirely a wrong and unnecessary proceeding. There are few children that cannot afford to wait for twelve or even twenty-four hours. The proceeding is also hurtful, leading to irritation of the child's stomach, and the production of wind, colic, and other evils. In every case the child should be put to the mother's breast, immediately after it has been washed and dressed, if the mother is not too tired, and at latest within an hour or two after birth. It often needs the exercise of some little patience before the child obtains a proper hold of the nipple. It should be aided by the nipple being drawn out with the fingers and moistened with milk. If there is milk in the breast the child will obtain satisfaction, and will soon relax its hold and drop off to sleep. The nipple should be removed from its mouth and dried to prevent hacking. But if no milk has been in the breasts, some advantage is yet gained in the drawing out of the nipple, and in the stimulus which has been given to the gland to hasten its activity. Between two and a half and three hours after the last suckling the child must again be put to the breast, and this is the

NURSERY APPLIANCES.

Plate VIII.



proper interval between each period of suckling for the first ten days or a fortnight after the birth. Regularly as the clock comes round towards the third hour, *night and day*, for the period named, the child is to be lifted to its mother's breast. This is the first rule of infant nursing. It must not be broken for any reason. It is a great temptation, if the child is sound asleep, to let the hour slip past; and many are proud to tell how the child slept for five or six hours on end. This is a mistake. The child must be wakened at the hour and sufficiently roused and kept awake till it has taken a proper quantity of milk, when it will, in all probability, drop off at once to sleep again. On the other hand if it has been allowed to sleep for five or six hours, the chances are that wind has collected in its stomach and bowels, and its next drink will be followed by an attack of colic and a screaming fit. The mother or nurse will pay dearly for her five or six hours' rest by half an hour's entertainment of this sort. If, on the other hand, the rule is strictly followed, the child will fall in with the regular ways almost naturally. Within a couple of days the mother will have no need of a clock to regulate her suckling. The child will wake up at the hour with almost perfect regularity, will go to sleep after its drink almost immediately, and in ordinary circumstances will give no trouble whatever. Each breast should be given alternately. Often one nipple is hacked and very painful, and the mother shrinks from giving that breast, and delays. This is a most serious mistake, and the greater evil of a "gathered" breast may be the result. To prevent such results the slightest crack of the nipple should be treated thus: carefully dry the nipple after each suckling and place over it a pad of cotton wool, the centre of which is soaked with glycerine of tannin (obtained from druggists). Before the child is again put to the breast remove the wool and bathe off the glycerine of tannin, which is again applied when the child is removed. If this is not sufficient to heal the hack, then let the mother secure without delay a glass nipple shield with india-rubber tube and teat attached, as shown in the Plate of Nursing Appliances. Usually the shields are sold with the teat on the end of the glass, no tube intervening. It is better to have the tube, because by it the mother may apply the shield and herself suck till the milk fills the tube, then putting the teat into the child's mouth. Thus the child is not worried by sucking in vain for some time. The shield should be worn at each suckling, and the wool with glycerine of tannin applied in the interval till the nipple is quite healed.

Usually mothers err by giving the child drink too often. If the child is the least peevish or fretful, the nipple is forced into its mouth to stop its crying, and the child, whether hungry or not, instinctively begins to drink. Should the fretfulness have been caused by the uneasy feelings of an overloaded stomach, this only increases the evil.

The mother must also take care that the child does not drink too much at one time. It usually indicates itself when it has had enough by withdrawing from the breast. It should, therefore, be allowed to drink till it voluntarily leaves off, and should not be urged to resume it again. If, as is frequently done, the nipple be again put into the infant's mouth, the mere contact calls into play the instinctive act of sucking, with the result that more milk than is needed is taken, the stomach is overloaded and may soon indicate this by rejecting some of its load, or, if it remain, the child is uneasy and restless for some time afterwards.

It sometimes happens that a proper flow of milk is not established for several days after the birth of the child. It may be no milk is forthcoming for a day or two. In these circumstances the child should still be put to the breast occasionally to excite the gland, but it must also be regularly fed. For this purpose a mixture of one-third cow's milk and two-thirds warm water, barely sweetened with loaf-sugar, or, better still, sugar of milk, is the best. It should be given, *not by spoon, but through an ordinary feeding-bottle*, to accustom the child to the use of the nipple. As the mother's milk is gradually formed, the supply of this mixture should be diminished, till, with an abundant supply of the former, the latter is entirely withdrawn.

The first breast milk is of a peculiar character. It is thicker and of a yellower colour than ordinary breast milk, and is called **colostrum.** It usually acts upon the child's bowels, and aids the expulsion of the material present when the child is born, which is usually of a dark offensive character. It is beneficial, therefore, to the child to get this first milk, and *it makes it unnecessary for the child to have any other opening medicine.*

A nursing mother will not take long to discover that the qualities of her milk vary with her state of health, and with the character of her diet. If she is honestly doing her duty towards her child, she will soon regulate her own food by the one condition of its agreeing

with her infant. Her food must be abundant, for it must supply the wants of herself and her child. The intervals between each of her meals ought not to be too prolonged. Four hours or thereby is as long an interval as is advisable. If she has fasted long, and, before herself taking food, suckles her infant, the child is apt to be disturbed and uneasy. The food should be plain and nourishing, abundance of milk, bread and milk, porridge and milk, milk puddings, eggs, fish, soups, flesh and fowl, prepared in simple methods. Highly spiced dishes, with pastries and puddings, green vegetables, uncooked fruits, cheese, &c., are very likely to call forth very strong objections from the child. Every mother, however, must determine for herself what she can safely take, so far as her child is concerned, for what one mother dare not take without exciting screaming fits in her child, another mother can take without her infant being the least disturbed. As a rule stimulants are not necessary or desirable. If, however, a mother has reason to believe that her milk is not sufficiently nourishing to the child, its quality may often be improved by her taking about one-third of a pint of good stout to dinner, and perhaps the same quantity towards evening.

The milk is profoundly affected by the mother's state of mind and body. If she has been over-fatigued, if she has been worried or annoyed, her child is likely to suffer, and to add to her troubles. But nothing so quickly and seriously affects the quality of the milk as sudden emotion, passion, or excitement of any kind, a sudden fear, or fright, &c. The bad effects exhibited in the child are sometimes extremely serious and prolonged. Therefore a mother should endeavour to maintain an equable and calm frame of mind. She should avoid all undue excitements, pleasurable or painful. She should always have her due amount of sleep, and a daily moderate amount of exercise. The quality of the milk is affected by another circumstance. As a rule so long as the mother continues nursing her monthly illness does not return, and also as a rule she does not become again pregnant. But the rule has numerous exceptions. It is very seldom that the monthly illness of a nursing mother returns soon after delivery, but not so uncommon for it to return about the sixth or seventh month. During the period of the illness the milk is impaired in quality, and the child is likely to be fretful and its digestion to be disturbed. If this happens while the infant is still quite young it may necessitate the mother giving up nursing, but if the child is already six or seven months old it need not cause any inconvenience. The child is probably already having some artificial feeding, and during the period of the illness the breast may be withheld more than usual. It rarely happens that pregnancy occurs during nursing except towards the end of the nursing period. If it do occur nursing must be given up.

To repeat: *up to the age of four or six months the child is to be fed entirely by its mother's milk; it should be put to the breast at regular intervals of about three hours at first, nothing, neither the child's sleep nor the mother's, being allowed to interfere with this arrangement, which is carried out by night as well as by day; after ten days or a fortnight, the child being healthy and vigorous, the interval may be slightly lengthened through the day, and lengthened to four hours during the night.* After a month or five weeks it will often, by judicious management, be possible for the mother to arrange to have a moderately long night's rest, uninterrupted. If the child is suckled about 10 or 11 at night, it may be allowed to sleep on till 4 or 5 in the morning, without a further supply of food. If the child is ordinarily strong, the mother will be able by the exercise of a little patience and perseverance, to gradually train the child to this habit; and its value for herself is very plain. But she will only succeed by herself being strictly regular in suckling the child at the proper times.

Should there be, as there often is, any sufficient reason for a mother not suckling her child, there are two methods of rearing the infant. The one and by far the more preferable method is to secure the services of a wet-nurse. In many families the expense is a fatal objection to this method, however desirable it may be. The second method is to rear the child with artificial food, to rear it "by hand," or to "bring it up on the bottle," as people say.

The choice of a wet-nurse should be made with care. She should be in evident good health, but should also be carefully examined to be sure that she is free from any communicable disease, like consumption and syphilis. For this purpose her teeth, gums, throat, skin and hair, and glands of the neck should be inspected. It is well also to learn the character of her husband, and his state of health. Her breasts should be firm, and should have the knotty irregular feeling of glandular structure, not fat and flabby. The nipples should be well formed, and free from fissures. In order that her milk should be suitable, as regards age, to the child,

she should have been herself confined about the same time as the mother of the child she is about to nurse, and rather later than earlier. Her milk should be examined. It should be bluish-white, sweetish, and should yield on standing a considerable quantity of cream. *The best test of the excellence of the nurse is the appearance of her own child.* If it present any skin eruption, cracks or fissures of the mouth or nostrils, or blotches about the buttocks, she should be rejected.

The wet-nurse should follow the same rules as to frequency of suckling the child as have been laid down for the nursing mother, and her own habits of life must be carefully regulated. Her food should be plain, nourishing, and at regular intervals. She ought not to need stimulants of any kind, neither porter nor beer. She ought to be cleanly in habit, ought to go early to bed, and rise early. She should have stated daily exercise. *Next to the quality of her milk, the quality of her temper is of the most importance.* A bad temper ought to be a fault not possible of being overlooked. It is a strong objection to continuing a wet-nurse if her monthly illnesses return. It ought to be unnecessary to add that the wet-nurse should be carefully and constantly superintended, no matter how trustworthy she may be.

Artificial Feeding.—If a wet-nurse be for some reason or other not obtainable, then the child must be brought up "by hand." *Milk must be prepared so as to resemble as nearly as possible what the mother's milk would be.* Asses' or goats' milk affords the nearest approach. It requires being diluted with water, but no sweetening. Cow's milk, however, is that most easily obtained and most generally used. When artificial feeding becomes necessary it is of the utmost importance that milk of the same cow be regularly obtained, and to secure this arrangements should be made with dairy people who themselves keep cows. For the newly-born infant one part of cow's milk should be mixed with two parts of boiling water, sugar (preferably sugar of milk, obtained from druggists) being added just slightly to sweeten. The mixture should be given through a feeding-bottle. It should be made freshly every time the feeding-bottle is replenished, none being added to the bottle while some milk is still in it. Before each refilling, the bottle, cork, &c. should be carefully cleaned with boiling water, and a fine brush should be used for cleaning the tubes. In fact, after being used, the bottle and tubes should be scalded with boiling water, and then laid aside in a basin of pure cold water till again required. After the first fortnight equal parts of water and milk should be used, as the strength of the child may indicate, and gradually the amount of water diminished, till about the sixth month pure milk is being given. The milk *should be given at the same degree of warmth as the mother's milk would be.* Tested by a thermometer this would be about 98° Fahr. A suitable heat is obtained by diluting the cow's milk with hot water in the proportions named. It may also be managed by placing the feeding-bottle with the mixture in it in a basin of warm water.

As to the quantity required by the child, it is not well to adhere too sternly to hard-and-fast rules. If the child is well managed it will itself be a thoroughly reliable informant as to the needed quantity. As soon as it has had enough it will show a disinclination for more, and this indication ought to be at once accepted and no further supply urged on it. It should get its drink every three hours during the day, and every four or so during the night, for the first several weeks after birth, just as the sucking child does, and if regular habits like this are encouraged, it will take its due supply, no more and no less, and go to sleep again. As it grows older it will desire more at a time, and the intervals may be lengthened. So that a healthy well-managed child will itself quite plainly tell what quantity of milk it needs. As a rule, however, an infant takes from the breast about six table-spoonfuls of milk at each suckling during the first and second months of life. Week by week it takes more and more till, at the age of ten months, it will draw three quarters of a pint and upwards. By the end of the first month an infant fed by hand should be taking upwards of a pint (a pint is equal to 20 ounces—or 4 gills), say 5 gills in 24 hours. At the end of two months it should have nearly a pint and a half, between 5 and 6 gills. At the end of three months it should have between $1\frac{1}{2}$ and 2 pints, between 6 and 8 gills, and so on.

It often happens that cow's milk does not agree well with the infant. It is certain that a child "brought up on the bottle" does not, as a rule, thrive so well as one brought up "at the breast." The child often vomits the milk soon after it has been swallowed, and is affected with colic and looseness of bowels. The milk, as vomited, is usually in large curdled masses. Now the curdling of the milk in the stomach is the first stage in the process of digestion, is a natural process, therefore, and

does not indicate anything wrong, as many mothers and nurses suppose. But cow's milk curdles in larger and more solid masses than human milk in the process of digestion. Human milk forms finer and more flake-like curd. The large solid curd of cow's milk is, therefore, more difficult to digest, and more liable to irritate an infant's stomach than the soft fine curd of human milk. If there is any difficulty in getting the cow's milk to agree with the child, it is well, first of all, to try the effect of boiling the milk before using it. The effect of boiling seems to be to cause the milk when it reaches the stomach to curdle more slowly and in smaller masses. Before trying any other course, however, the mother or nurse ought to assure herself that there is not some simple and obvious reason for the milk disagreeing with the child. She ought to see that the child is not being fed too often, that it is not getting too much at one time, and so on. Many get into the extremely bad trick of quieting a child, on the least suggestion of its crying, by thrusting the teat of the feeding-bottle into its mouth. They allow the bottle to lie by the child's side in the crib, and permit it to suck, at odd moments, all day long, letting it even drop off to sleep with the teat in its mouth. This is purchasing domestic peace at the price of the child's health. For there is no surer way, in the long run, of completely disturbing the child's digestion, and of setting up indigestion, colic, looseness of bowels, sickness and vomiting, than this. Therefore, before mother or nurse concludes that the milk is not agreeing with the child, let her see that no such bad practices as these enter into the question. If the milk is still vomited, let the child be fed with small quantities frequently repeated. For a day or two let it have two tea-spoonfuls of the milk every 20 minutes or so, and nothing else. Find, in short, the smallest quantity that the child's stomach can tolerate at one time. The smaller the quantity, the more often must it be given. The chances are that speedily all vomiting will cease. After it has stopped for a day or so, gradually increase the quantity given and lengthen the intervals in proportion. The probabilities are that, if this method is carefully pursued, in a few days the child will be taking the ordinary quantities of milk at the proper intervals without any bad symptom. If, however, it is impossible by such means to get the cow's milk to agree with the child, a change must be made. If goat's or ass's milk can be obtained, let it be used, diluted, but not sweetened. Failing this, let condensed milk be employed. Most of the condensed milks contain a large quantity of sugar to aid in their preservation. It is best to get unsweetened condensed milk. It does not, however, keep long, and must be rapidly used. It must not be given too strong. For an infant at birth one tea-spoonful to one tea-spoonful and a half to the ordinary teacupful of warm water ought to be sufficient; and the strength should be gradually increased, as is done with ordinary cow's milk, till at six months of age the child gets a mixture made of 1 part of the condensed milk to every 8 or 10 of water. The unsweetened kind requires, of course, slight sweetening with fine loaf-sugar.

A great many attempts have been made to produce a food for infants resembling human milk, Liebig's food for infants, Nestle's food, &c. &c. As a rule, however, they are all deficient in nitrogenous elements; as a result, although they agree with children, the children are soft, flabby, pale, and deficient in vigour. They have soft yielding bones, are very open to disease, and have no great power of recovery.

In no sort of food is this defect more marked than in such as arrowroot and corn-flour, and to a less but still a marked extent, in sago, tapioca, rice, barley. Yet it is a popular delusion that arrowroot and corn-flour are good for children, and very nourishing. *They are not so.* They consist almost entirely of starch, which the digestive apparatus of an infant is not yet prepared to digest. They are bland in character, however, and are not irritating, but are only nourishing in proportion to the quantity of milk with which they are prepared. So far as the arrowroot or corn-flour themselves are concerned, a child fed mainly on them would waste, would be literally starved.

Oatmeal is nourishing, and in the form of oat-flour, of which good kinds are now to be had, is very suitable even for infants. It should be made as nearly entirely with milk as suits the child's stomach. Entire wheat-flour is now made of a very fine kind for infants and invalids, and is one of the best kinds of such food-stuffs. Biscuit-powder is also manufactured for infants' use by well-known and reliable firms. A useful biscuit-powder is easily obtained by rolling a tea-biscuit of good quality into powder by means of a rolling pin. One or two tea-spoonfuls mixed with equal parts of milk and water and a little sugar and brought to the boiling point offers a very good food for infants. It may be thinned with milk and given from a feeding-bottle.

For purposes of night feeding food warmers

are employed. A useful kind is figured in the Plate of Nursery Appliances. It is usual to keep the food in the dish and the light burning beneath it, so that the food is kept warm all through the night. Kept warm for hours at a time the milk is apt to sour. It is better, therefore, to light the wick and allow the food to warm just before it is about to be used, the food being kept cold till then. For a similar reason it is a mistake to fill a feeding-bottle with milk and keep it warm in bed till required. Changes are thus apt to be produced in it injurious to health.

It is necessary again to repeat that milk is the proper diet, and milk only, for a child up to four and even six months of age, and that, as a rule, if the mother or nurse takes sufficient care in regulating the times of feeding and the quantities, difficulties in the way of digestion will be overcome. It is also necessary to say again that the utmost care must be exercised in keeping the feeding-bottle, tubes, and teat scrupulously clean. A speck of old milk, left in either, will speedily set up fermentation in the new supply, and derangement of the child's stomach, looseness of bowels, &c., are too likely speedily to arise.

Bathing and Clothing.—Nothing conduces so much to the comfort and health of a child as regular bathing from the first day of its life. The infant should have its first bath immediately after its birth. The bath should be large enough to permit the child to be covered with water up to the neck. The water should be at the same degree of warmth as the child's body; lukewarm is the best description of it. If regulated by a thermometer, it should be about 98° Fahr. The child's head and face should be first washed with the clean bath water, and then thoroughly dried with a soft towel, the child meantime lying on the nurse's lap on a warmed flannel cloth. The child should then be placed bodily in the bath, supported by the nurse's hand and arm, and gently sponged all over. A small quantity of fine toilet soap should be used. Special care should be taken to cleanse thoroughly the fold of skin at the neck, armpits, and groins. After the washing the child should be quickly but carefully dried, and then those parts of the skin which rub against one another, the folds of the groin, armpit, neck, &c. should be lightly dusted with fine violet powder. A great many nurses are careless in the drying, thinking the dusting powder is put on for this purpose. This is a great mistake. If the powder is put on the skin still damp it forms a cake; and nothing is more likely to irritate and inflame the child's tender skin and lead to the formation of sores. The skin must first be quite dry, and then the powder applied helps to diminish the friction between the opposing surfaces of the skin. For a similar reason the powder must not be too freely applied, a very fine film of it being all that is necessary.

The bathing process should be performed before a fire, draughts being kept off by a screen.

The newly-born infant often has its skin coated in various places, and specially the head and folds near the joints, with a thick whitish scum difficult to wash off. This is most easily removed with oil, olive-oil, sweet-oil, or butter, if no oil is at hand. The nurse takes a little oil in the palm of her hand, and rubs it over the part gently but firmly till a sort of lather has been produced. A sponge with clean water and a little soap will then readily cleanse the skin. The eyes of a newly-born infant should be specially looked at, every particle of matter being removed with a clean sponge and pure warm water. Any appearance of matter coming from them within the first few days after birth should cause special attention to be directed to them. (See INFLAMMATION OF THE EYES OF NEWLY-BORN CHILDREN, p. 458.)

Children should be bathed twice daily, in the morning immediately after rising and in the evening before going to bed, and *always at the same hour*. In fact if the same regularity advised in regard to the giving of food be practised in regard to the bathing, it will add much to the comfort and general health of the child, and will do a great deal towards making the child bright and active throughout the day, and towards securing for it sound refreshing sleep throughout the night.

The evening bath should be the principal one of the day, the child's body being then well washed all over, soap being used; the morning bath need not be much more than a dip in plain water, and sluicing with the sponge. As the child grows, the warmth of the morning bath may be gradually reduced a little, and at six months the child, if it is healthy and vigorous, may be freely sponged in the morning with nearly cold water if the weather is warm. The cool water should only be applied with the sponge, the water in the bath in which the child is set down should be warmer. After the cold sponging the child's body should be well rubbed with a fine towel; and if there is any

sign of chilliness or blueness of the skin, the cold sponging should be stopped and not used again till the child is older. No mistaken notion of "hardening the child" should lead to persistence in the use of water manifestly colder than is consistent with the child's comfort.

Food should be given *after not before* the bath.

Many mothers and nurses abstain from giving the usual bath for very trifling reasons. If the bath is properly given, and if proper care is taken to guard against chills, which ought always to be done, there are very few circumstances, indeed, in which it can do any harm. On the other hand, at the outset of many childish complaints, the warm bath is of the greatest possible benefit. It not only cleanses the skin, and stimulates the activity of the sweat-glands in removing waste substances from the blood, but it causes relaxation of the blood-vessels of the whole surface of the body, and consequently brings the blood to the skin in greatly increased quantity to the relief of deeper parts.

Clothing has for its object the maintenance of a certain regular degree of warmth, and its nature and amount ought, therefore, to be determined by the external temperature. It should vary, that is to say, with the climate and the season of the year. In section XI. it has been explained that the skin plays a very important part in maintaining a regular bodily temperature. When the heat of the atmosphere is higher than the proper bodily heat, it has been explained that the body heat is kept at its due level by the blood flowing in larger quantity to the skin, and by heat lost in evaporating increased perspiration; and when the heat of the atmosphere is less than that of the body, a lowering of the bodily temperature is to some extent prevented by the contraction of the blood-vessels of the skin, diminished sweat, and consequently a diminution in the loss by evaporation. In climates where the heat of the atmosphere is very different from that of the human body, and where the variations are great, men must come to the aid of the ordinary healthy processes of the body. In warm climates clothing is used which reflects, throws off, as much as possible, the heat of the sun, and is, at the same time, fitted to permit of free perspiration, while in cold climates clothing is used to retain the heat of the body and prevent it passing off. While infants' dress ought to fulfil the same purposes, it must be remembered that the heat-regulating apparatus, so to speak, of the child's body is not yet in full working order, and the child is consequently much more sensitive to changes in the surrounding atmosphere, and much more strongly affected by them. A slight change in the heat of the atmosphere, to which a man's body so readily adapts itself that he is barely conscious of it, may strongly affect a child; and this should always be remembered by mothers and nurses.

The second special point to notice regarding infants' dress is that it should be so put on as to interfere as little as possible with all natural movements. This requirement is not satisfied when free movement is permitted to arms and legs; care must be taken that the movements of breathing are not hindered. Most of mothers and nurses make this mistake at the very outset. They apply the binder so tightly round the child's belly and chest, in the delusion that its back is thus supported, that its breathing is greatly impeded; and often permanent injury is inflicted on the lungs. Acting under the same mistaken idea they encase the child's body in stays (so-called), and with a multiplicity of other wrappings reduce the infant to a condition of miserable bondage. A third point worth remarking upon is that an infant's skin is not only very sensitive to changes of temperature, but is also very readily irritated in various ways. The mere mechanical irritation produced by the rubbing of rough cloth, will often cause the appearance of a rash on the skin, and will at least be a source of great discomfort to the child. This is a cause of annoyance not to be overlooked in dealing with a fretful child. For this reason the child should have next its skin some very fine soft material. For the same reason wet napkins should be quickly removed, as well as any other article of dress that has become damp. The skin is very speedily inflamed, and cracks and fissures are very readily caused, by contact with wet clothing, especially when wet with irritating material such as that of the discharges. Before replacing dry napkins the skin should be carefully dried and dusted, if previously sponged so much the better. It may be added that the napkins or diapers should not be washed in water containing soda. Pins, even safety-pins, should, as far as possible, be avoided in an infant's dress. Extreme restlessness, crying, and sometimes even convulsions have been caused by carelessly applied pins, whose points had worked themselves into the child's skin.

What manner of child's clothing, then, best

fulfils the conditions that have been set forth? Flannel ought, undoubtedly, to form the chief part of an infant's dress, a long-sleeved flannel gown from the neck downwards being the principal garment. As, however, the child's skin is apt to be irritated by rubbing against the flannel, a shirt of fine lawn is usually put on next the skin. It is customary also for a roll of flannel—a binder—to be wound round the belly. During the early weeks of the child's life this is valuable, by giving protection and support to the navel. *But it is almost constantly too tightly drawn*, and seriously interferes with the action of the chest and belly, greatly impeding breathing. It should always be so slack that the hand can be readily passed between it and the skin. The use of the binder should not be continued longer than six or eight weeks. After that time it should be daily made narrower and shorter till in a few days it is entirely given up. The flannel dress should be fastened by means of buttons or tapes, even safety-pins being not devoid of danger, and it should extend for 10 inches or so beyond the feet to keep the legs warm. It should never be so tight-fitting at any part as to limit freedom of movement. A light woollen shawl, to be thrown over the child when it is being carried from one part of the house to the other, completes all its necessary clothing. The head needs no special covering indoors, either by day or by night. When the child is taken out, it requires a covering for the head, a soft, light woollen hood being preferred, and it also needs an extra wrap, a woollen shawl being the best. If a cloak is used, the mistake should not be made of fastening it on by tying round the neck only, half strangling the child, as it too often does. The thickness and closeness of the material forming the added garment should depend upon the weather and season of the year. About the third month of life, when the child begins to exercise its limbs more freely, its clothes are usually shortened. Stockings and soft pliable shoes become necessary. The clothing at this period commonly consists of a linen, cotton, or flannel shirt next the skin, of a pair of stiff-starched cotton stays, of a flannel petticoat made with a body, an outer cotton one, and of a dress with short sleeves. There are some objections to be taken to this arrangement. The shirt should always be of flannel, unless that has already proved too irritating. The stays are worse than useless, they are positively injurious, a hindrance alike to free movement and free growth. There is no justification of any kind for retaining them. Instead of each petticoat having a body of its own, or being simply buttoned at the waist, a light flannel body should be made separately. Round the waist it should be provided with buttons to fit corresponding button-holes in the petticoats. With this arrangement, if one petticoat be wet it can be removed at once without undressing the child. From the waist-band of this body suspenders for stockings can be attached. The dress should always have long sleeves, and should not be low-necked.

For night a woollen night-dress should be provided, but no night-cap or other covering for the head.

Exercise, Air, and Sleep.—Even the very young infant derives great benefit from such exercise as is directly possible to it, as it lies free and unrestrained on its mother's or nurse's lap. For this reason the washing and dressing of a child should be leisurely rather than hurriedly performed, provided care be taken against the risk of cold. Even the youngest infant should be accustomed to the open air, carried in its nurse's arms. The daily airing should be a regular ceremony, on dull as well as on bright days. The child should have extra clothing according to the season and the state of the atmosphere on the particular day; and the face should be protected by a light veil. With such precautions the child will not be affected by moderate changes of weather; and it will seldom be necessary to prohibit its going out. At first, of course, the infant is to be taken into the open air for only a few minutes at a time, fifteen to twenty, and the time is to be gradually extended as seems desirable, and according to the state of the weather. Carrying in the nurse's arms is better than wheeling in a perambulator. The motion of the perambulator is not so agreeable, and the child is apt to become stiff and chilled in a constrained position.

As regards rest, the infant passes most of its time asleep, and it is, therefore, important to make no mistake regarding its bed and bed coverings. From its birth the child should sleep in its own bed and *not with its parents or nurse.* A wicker basket, lined inside, provided with a firm mattress, covered by a small blanket, a small, not too soft, pillow, and a miniature pair of blankets and down quilt, form a very comfortable sleeping-place. The bassinet should be raised off the floor. Children are commonly kept too warm in such little cots, coverings being heaped upon them, curtains being drawn round

their heads, so that they are often completely covered up, no regard being paid to the means by which fresh air is to reach the child. As a result when the child is lifted out of the bed, it is streaming with moisture, its head being bathed in perspiration. Care is certainly to be exercised to prevent draughts sweeping below the crib or round its head, but the basket should be freely open in front towards the child's face, which should never be covered up. Perspiration bursts out over the child's head if the pillow is so soft that the head sinks down into it. Down pillows and mattresses are, therefore, bad. The pillows and mattresses should, on the other hand, be firm enough to offer sufficient though gentle support to the child.

The excessive warmth to which the child is usually subject in its cot is not so injurious even as the bad air which it is so frequently caused to breathe. Not only, therefore, must curtains not be drawn round its head, but care should be taken to ensure that the room in which it sleeps is duly and properly ventilated, but so as to avoid draughts. The opportunity should also be taken whenever the child is out of the apartment to air it properly. The room should be directed to the south, if possible, and air and sunlight should have free access to it, for air and light are as necessary for healthy growth as food. It is always advisable to regulate the warmth of the room by means of a thermometer, instead of leaving it to the feeling of parent or nurse, and the heat should be kept as regular as possible, the mercury standing at 65° Fahr.

Use of Medicines.—As a general rule if infants are properly managed they require very little medicine of any kind. But with many people it is a matter of custom to give a dose of castor-oil, or magnesia, at regular intervals, every two or three days, or once or twice a week. According to their view, the child could not possibly continue well without such meddlesome interference. From the day of its birth onwards for the slightest reason, and frequently without reason, the child is dosed with opening medicine. The result is that irregularity of the bowels is set up, and a great amount of harm done which it is very difficult to rectify. Now a healthy infant needs no medicine whatever as a matter of course, and the giving to it of medicine of any kind ought to be an unusual rather than a customary practice.

The first milk drawn from the breast of a nursing mother is of a peculiar character and is called **colostrum**. It has an opening effect on the child's bowels, and the first material passed from the child is usually of a dark brownish colour. There is, therefore, no necessity for the newly-born child, that is being nursed by its mother, getting opening medicine, for that has already been provided for *by nature*. This is one of the reasons why the child should be put to its mother's breast shortly after birth. After this the child's bowels ought to move naturally twice or three times in twenty-four hours, and the stools should be of the thickness of thin mustard, of a light yellow colour, free from lumps or curdy-looking masses, and passed without pain or disturbance of any kind. Frequently the motions are greenish, very offensive to the smell, and lumpy with white portions of curd, and to remedy this it is usual for the nurse at once to resort to the use of castor-oil, magnesia, or other medicine of a like effect. Now the cause of this condition is commonly bad methods of management. The child is geting too many drinks, or too much at a time. The curd is simply portions of undigested milk passing unchanged through the bowels, because the bowels are unable to digest the large quantity passed into them at one time. The remedy, at least in the first instance, is to correct the bad nursing, to give the child the breast less frequently, or to give it less at a time, or to do both these things. If the mother or nurse will really put it to herself that she is to blame for the state of the child's digestion, and will correct the mistakes she is making in suckling, the natural condition may be restored without the use of medicine. One of the results of this improper feeding is that the infant is troubled with wind and is much pained. For that reason, also, the mother hastes to give medicine instead of setting right her improper ways of nursing. If, however, the bowels continue for two or three days in this state, and the child is very fretful and uneasy, it may be desirable to give one dose of medicine, effectually to clear out the bowels, and permit a fresh start. For this purpose one or two tea-spoonfuls of castor-oil are the best means. But the mother must not forget that the relief will only be temporary, unless she takes care to manage the child better for the future. The same general principles should be the guide in rearing a child that is being brought up on artificial food. Here, it may be necessary to give medicine to secure a motion within the first two days after the child's birth, because it is not getting the benefit of the first milk of its mother. Castor-oil is here again to be given, and thereafter regularity of the

bowels is to be secured by attention to the feeding rather than by any giving of drugs. There are numerous cases where from its birth the child exhibits a tendency to costiveness, the proper methods of treating these cases are mentioned further on (p. 462). *The rule to be remembered, however, is that regularity of movement of the child's bowels is to be secured by proper feeding and not by medicines.*

Opening medicines are also the common resort when a child seems troubled with any irritability of the stomach. If it vomits its milk, and specially, of course, if this happens frequently, it must be dosed with some drug or another. Here, again, in all probability the fault is the mother's. It is commonly an overloaded stomach that is indicated; the child is allowed to take, or is forced to take, too much milk. Perhaps the mother's breasts are very full, and the milk flows so freely that the child can scarcely drink fast enough, and gulps it down, or perhaps the mother puts the nipple again and again into the infant's mouth, and encourages it to take more, when by withdrawing its head, it has already indicated its satisfaction. In such cases the vomiting is simply nature's method of disposing of the excess. When mothers see this, their business is to try to make the child drink more slowly, to take away the breast when they think the child has had enough, and never to urge it to take an extra supply. As soon as this has been done, probably the vomiting will cease. If, however, medicine does seem needful, then it ought to be a simple dose of one or two tea-spoonfuls of castor-oil, or two or three tea-spoonfuls of fluid magnesia repeated occasionally for a day or two.

Many people find it very difficult to give medicine to infants. The child can easily be held on the left arm, propped up with its head resting on the shoulder and held so by the arm gently pressing the head against the person's chest, the hand of the same arm being brought round in front to hold down the infant's hands. The medicine is taken in a small spoon in the right hand, and gently, but firmly, introduced into the mouth far enough to place the medicine well back on the tongue. If this is properly done the child cannot help swallowing it. *Only a small quantity should be* taken on the spoon at a time, about a quarter of the spoonful, and when that has been disposed of a little more is given, till the necessary quantity has been swallowed.

A second thing which some nurses are too ready to do is giving the lately-born infant a little gin and water or a little spirits of nitre and water, because the child has not made water, or what they think not enough. This must never be allowed. A small quantity of water may be made but be unnoticed, because of being soaked up by the cloths. Even though it is quite certain that no water has been made, drugs must not be given. A pad of flannel wrung out of moderately warm water and placed over the lower part of the belly and between the legs will usually be sufficient to encourage the flow. This application may be repeated for several times. Nothing else should be done without medical advice.

Stimulants of any kind should never be given to children by parents or nurses. A doctor may find it advisable to administer them in certain cases, but on no account should others employ them without medical orders.

Some form of stimulant is often given to dispel wind, but there are some harmless drugs, such as dill water or essence of anise, which are equally satisfactory in their action. The method of giving them is mentioned on p. 461. But again it cannot be too strongly insisted on that flatulence and similar disturbance of the bowels are due most frequently to bad management in suckling or feeding, and that that evil should be rectified. The practice of giving to children, and specially to infants, what are insinuatingly called *soothing medicines* cannot be too strongly condemned. The effective ingredient in the most of these compounds is *opium* in some one of its forms. Laudanum itself, the tincture of opium, is frequently given on sugar by unscrupulous nurses or careless mothers, to quiet a fretful child, whose pain, restlessness, and sleeplessness are due to wretched mismanagement or gross inattention. Even mothers who would not dream of giving laudanum or opium to any of their children are glad to make use of preparations in which the opiate is masked by some special name, such as Mrs. Winslow's Soothing Syrup, Godfrey's Cordial, Dalby's Carminative, syrup of poppies, &c. &c. In each of these it is the contained opium that produces the so-called soothing effect, and each is capable, if used in sufficient quantity, of inducing a "quietness" that will not again be broken. *One drop* of laudanum has killed a child, and numerous cases of infants' deaths have been reported in medical journals from the use of Mrs. Winslow's remedy, and from such preparations. Medical men themselves are extremely chary of administering opiates in any

form to young children, even in cases of serious disease where their use seems demanded, and when they do feel compelled to use them they are extremely careful in prescribing the dose and in watching its effects. *Children are extremely susceptible to the action of opium.* This must never be forgotten, for of some other drugs, of which *belladonna* is a good example, they can "stand" a larger quantity than most grown-up persons. It ought then to be a rule, never departed from, that neither opium nor any of its preparations, nor any compound in which it exists, is ever to be administered by mother or nurse to a child. Mothers who intrust their children largely to the care of nurses, cannot be too careful in seeing that the nurse does not *secretly* employ such remedies to give herself greater ease and convenience by drugging her charge to sleep.

To sum up, the only medicines parents or nurses need have at hand are castor-oil, magnesia, and dill water. If they are kept at hand in case of being required, they should, nevertheless, be sparingly used. The child, it may again be repeated, ought not, in ordinary cases, to be *restored* to a proper condition by the use of medicines, but ought to be *kept* in a healthy state by proper feeding and general careful and watchful management.

Premature children.—It is only necessary to say a word or two about the extra care required for children born before full time. The more near the infants are to the full period of nine months, the greater is the likelihood of careful nursing enabling them to survive. It is a vulgar notion that a seven months' child has a better chance of continued existence than an eight months' child. This is not so. A child that has passed eight months within the womb is in every way more developed than one that has passed only seven months, and its chance of survival is consequently proportionately increased. The chance of a child born before the seventh month is comparatively small. Nevertheless there are numerous cases on record of infants, born between the sixth and seventh month of intra-uterine life, surviving and thriving satisfactorily. The two difficulties are those of feeding and keeping warm. The child is often too feeble to suck, and artificial feeding is necessary, because the mother has no milk. If the child can be made to suck, milk prepared as directed on p. 438 should be given from a feeding-bottle. To aid the child a small teat should be used, and the nurse should see that the milk can be drawn easily. The child should take from four to six table-spoonfuls at one time, and should get a drink at intervals of an hour and a half to two hours, and more frequently if a less quantity is taken at each time. If the child cannot suck, the milk must be given with the spoon, and it is better to give small quantities at frequent intervals, two to three table-spoonfuls every hour, than to attempt to give larger quantities less frequently. With premature children the difficulty of maintaining the bodily heat is great. To secure this it is sometimes necessary to surround the child, face excepted, with cotton wool. Care must also be taken with the skin, which is very tender, easily ruffled and inflamed.

Vaccination.—This is compulsory by law in Great Britain within the first six months of infant life. The purpose and value of vaccination have been fully discussed on pp. 406–409. It may be advisable to re-state here that a child should be vaccinated between the second and fourth month after birth, before teething begins, but that if small-pox be prevalent at the time, and if there be any danger of infection, it cannot be vaccinated too soon. *There is no risk at all to be compared to that of catching small-pox in vaccinating even the day after birth.* It may also be again stated that if the vaccine matter is taken from a healthy child on the eighth day after its inoculation, and if proper precautions be observed in taking the lymph to ensure that only lymph and no blood be taken, there can be no risks whatever of transferring any disease. Further, the extremely painful, red, and swollen arms that one occasionally sees are in most cases due to the carelessness of the mother or nurse in not properly guarding the arms from injury by rubbing or in other ways, and specially to badly-adapted clothes which compress the parts at the armpit and lead to inflammatory swelling of the whole arm. The full measure of safety is secured when four good vaccination marks are produced. The mother, therefore, should allow the child to be vaccinated on four "places" if she wishes the utmost benefit of the operation. Many doctors vaccinate only on two "places," and if the district where the children live and are likely to remain is commonly free from the disease, so that the risk of infection is slight, two marks may be satisfactory enough. Vaccination on only one place, however, is too little to be satisfied with. If, however, there is any risk of infection in the neighbourhood where the child lives, or if there is any likelihood of

the persons removing to any district where there is risk, vaccination should be performed on four "places" to secure the greatest amount of protection. If children are well managed they should give comparatively little trouble during the period when the vaccine is operating on the body. Careful dieting, the usual attention to bathing and cleanliness, attention to the bowels, and care to prevent injury and irritation to the arm, ought to ensure little disturbance. If the child suffers at all it will be between the seventh and tenth days, when it may be hot and restless, and the bowels slightly disordered. A tea-spoonful of castor-oil, or three or four tea-spoonfuls of fluid magnesia is all the necessary treatment. The heat of the vaccinated part may be soothed by placing lightly over it, if it seems needed, a piece of lint soaked in cold water, and keeping it soaked. If the lint is allowed to dry, it will adhere to the part, and attempts to detach it will cause still more pain than before.

Some children, comparatively few, however, fail to take the vaccination. By the Vaccination Acts the operation must have been performed three times and failed each time, before the child is declared insusceptible. If this has been done the doctor will give a certificate to that effect. But it would be well if the operation had failed twice with lymph obtained in the ordinary way, that it should be tried the third time with calf lymph.[1]

Should a child not be in good health, a medical man may, if he deems it advisable, postpone the operation to a period beyond the legal six months by signing a certificate to that effect.

Revaccination is considered on p. 410.

THE MANAGEMENT OF CHILDREN BETWEEN THE SIXTH MONTH AND SECOND YEAR OF AGE.

Food.—Up to the sixth month the child has either been nourished entirely by the breast milk, or by milk food given through a bottle, or by the breast milk supplemented by the bottle food. By this time it becomes necessary to make considerable additions to the diet. If the child is being suckled, and the mother has still a good supply of milk, the addition should consist of one meal per day, given about midday. It should be made of milk thickened with some well-boiled fine entire wheat-flour, or oat-flour, or ordinary wheaten bread boiled with milk and sweetened. Biscuit powder may also be used, or a scalded rusk. This should be made of a thickness that will permit of it being drawn through the bottle. A good food is made of the following:—

Malt	½ ounce.
Second Flour	½ ,,
Skimmed Milk	6 ounces.
Water	1 ounce.
Bicarbonate of Potash	7¼ grains.

Grind the malt in a mortar or coffee-mill; mix all the ingredients together; put in a pan thoroughly clean, and place by the side of the fire so that it becomes just lukewarm for 15 minutes; thereafter boil for 6 or 8 minutes; strain through a sieve or muslin, and give through a feeding-bottle. Some mothers, however, who regularly suckle their children, and have a strong objection to feeding-bottles, prefer to give such an addition to the diet in the form of spoon food, and there is no objection to this: the food only requires to be made thicker. Beginning with one meal a day of this kind, the child may soon get a second meal of a similar kind, the frequency of giving the breast being correspondingly diminished. If the mother's milk is rapidly diminishing, it is common to feed the child through the day, and give the breast only at night. It is better to give the breast once through the day and once through the night, and to give the other food at regular intervals between these times, contriving to give the last spoon or bottle food just before it is customary for the mother to retire so that she may not be disturbed till towards morning. It is too long an interval for the milk to stay undrawn in the breast between one night and the next, and therefore advisable for the child to be put to the breast once during the day. If the child is being brought up by hand, then the addition to the diet can be made at one of the ordinary times of feeding. In every case, however, the same regularity in respect of time of feeding, and the same care against overfeeding, must be exercised as have been already recommended in the management of the newly-born child. If one form of food disagrees with the child let another be tried. Derangement of the stomach and bowels is to be met by a change of diet rather than by the giving of medicines.

[1] There are several associations now in London for the supply of pure vaccine lymph, calf lymph as well as human lymph. The writer has had every reason to be satisfied with calf lymp obtained from the Association for the Supply of Pure Vaccine Lymph, 12 Pall Mall East, London, of which Mr. Ed. Darke is secretary. Half-tubes, sufficient for one child, are obtained through the post for 1*s.* 1*d.*

By the time the child is eight months old a further addition to the diet should be made by giving once a day a small quantity—a small teacupful at most—of beef-tea or weak chicken or mutton broth or soup from which all vegetables have been removed by straining through muslin and from which fat has been skimmed. The beef-tea is best made by scraping the meat with a knife. Place the scrapings in a jelly-can with two breakfast-cupfuls of *cold* water to each quarter of a pound of beef; set the jelly-can in a pot of hot water, covered with a lid, and allow the water in the pot to simmer for two hours or so. Salt the beef-tea to taste. It should contain all the valuable parts of the beef in fine flakes and should need no straining. If this tends to make the child's bowels too loose, that may be remedied by slightly thickening the tea with rice or corn-flour and boiling it for some minutes.

Weaning should be effected when the child is ten or twelve months old, the exact time being dependent upon the health of mother and child. It will be begun earlier if the mother is suffering from nursing, and delayed till later if the child is weakly and the mother able to bear prolonged nursing and having good milk. The period named is generally chosen because the child usually has about that time an interval of rest between cutting the front teeth and the first of those at the back. It is often a process involving some trouble to the mother and discomfort to the child, but, if the above directions as to feeding have been observed, the child will really have been in preparation for it since the sixth month, and much of the difficulty will be overcome. Weaning should not be allowed to take place if the child is suffering from the irritation of late teething, from any cold, or feverish attack, or trifling illness, but the mother should wait till that has passed off. The process should be performed gradually; as the breast-milk is withdrawn its place should be supplied by other appropriate nourishment. The child's food at this time should consist largely of milk and of the preparations of milk already mentioned, including well-boiled milk porridge, the diet being properly varied from day to day, though given at the same regular intervals, the cup of beef-tea or weak mutton broth being given once a day. At this time, too, a lightly-boiled egg beat up and properly seasoned, given with bread and milk, will be as a rule much relished. The mid-day meal may be thus varied, the egg being given instead of the beef-tea or broth. As the child grows older and more vigorous the quantity of animal food in the diet is to be carefully increased. At about fifteen months of age it may occasionally get a small quantity of well-boiled mealy potato, thoroughly bruised down in its beef-tea or in gravy, and the mid-day meal may also be added to by some light milk-pudding. Before this age no solid animal food whatever should be given. It will be receiving sufficient animal food in a semi-fluid form in the beef-tea, broth, beat-up egg, and so on. But between the fifteenth and eighteenth months the child may be tried with a little meat, if it be scraped down into a fine pulp and given with gravy and a little well-mashed potato. A small piece of chicken may be given in the same way. White fish will also be found usually to agree well with the child's digestion. At about two years of age the child should be getting four regular meals a day:—breakfast of well-boiled porridge and milk, bread and milk, or egg with bread (lightly buttered) and milk; a mid-day meal of beef-tea, broth, or soup, with a little well-mashed potato, and afterwards some light milk or egg pudding, or some well-chopped-up meat —beef or mutton—or fish or chicken, with potato and pudding afterwards; a tea of bread, butter, and milk, and the bread may be spread with jelly, honey, or syrup instead of with butter; and for supper bread and milk. Some regard should be paid in dieting to the relation of the meals to one another. If the breakfast consists chiefly of porridge and milk, or bread and milk, the dinner should contain a good proportion of animal food in the shape of egg, fish, or butcher-meat of some kind. For it must not be forgotten that at this age the child cannot obtain sufficient flesh-forming material from oatmeal or bread, and still less from rice, sago, corn-flour, or such substances. It cannot even drink sufficient milk to supply this want. The result will be that, if animal food is not supplied, the child will be soft, with soft bones and flabby muscles, wanting in sustained energy. The necessary animal part of the diet should therefore be made up at breakfast or dinner, and if, owing to the nature of this meal, on some occasion it is in deficient quantity, it may be made up at tea by a part of an egg or a whole egg. Animal food should be given preferably at mid-day. The meat should be boiled or roasted. Salted meats, pork, veal, and lamb are to be avoided. A small quantity of vegetable may also be allowed when the child has reached two years of age, potato as already mentioned being given earlier than that age, if

not new and if mealy and well mashed; but by two years carrot, turnip, and cauliflower, well boiled, may be permitted in small quantity, not cabbage or green vegetables. Soft green peas may be allowed. Some cooked fruits—stewed apple or prunes—will usually be relished given with well-boiled corn-flour or rice, but uncooked fruits are injurious, except the orange when in season, the child being taught to reject the skin and seeds. Pastry and nuts are to be avoided. The diet recommended will strike many people as generous, and liable to lead to overfeeding. It will not do so if the child receives its meals at regular times, and does not get additional food at odd moments. If a child has its regular meals it will take at each what satisfies it and no more, provided an undue variety of dishes be not produced to stimulate its appetite. But if in addition to its own meals it is permitted partly to share its parents', then overfeeding or digestive troubles will likely arise. As great an evil is the giving of sweet biscuits, pieces of bread and jelly, and so forth, between meals. Parents should from the first entirely set their face against "pieces" between meals. They prevent a healthy appetite at the proper meal-time, and derange the digestion besides. As a rule also sweetmeats are given very indiscriminately. An occasional sweetmeat is not hurtful, if only one be given occasionally. Those made entirely of pure sugar, or a gum pastille, or a small piece of chocolate may be given, *but only occasionally.* Any containing almonds, nuts, &c., should be avoided. Similarly, cakes with raisins, currants, &c., should not be given. Plain sponge-cakes or plain biscuits alone are admissible, but ought to be used at meal times as an addition to the meal, and not between meals.

Finally, children should be taught to take their food slowly and to chew it thoroughly.

The only **beverages** for children are milk and water. The practice of giving small quantities of wine, malt liquors, or stimulants of any sort for little ailments is hurtful in the extreme; still more is the habit of giving these things as a matter of course a most pernicious one. Stimulants should be given to children only on the direct order of the medical attendant, and then only in the small doses he orders, which should be carefully measured. As regards tea, many parents like their children beside them at table, for one meal at least, when they reach two or three years of age, and tea is often the meal. The child may have its cup of warm milk and water sweetened, and if it be barely coloured with tea no harm is done, but it ought not to be more than barely coloured. Thin cocoa, made mainly with milk, is, however, quite digestible for children and also nourishing.

Teething. The first set of teeth are called the **milk-teeth**. They have usually all appeared above the gum by the end of the second year of life, or from that to the thirtieth month. The full set consists of twenty teeth, ten in each jaw. The ten are formed of four central **incisors**, or **cutting** teeth, one **canine** or **eye** tooth at each side of these four, and two **molar** or **grinding** teeth at the back on each side. They appear on an average at the following periods:—

Two central cutting teeth, ...	7th month.
Two side, ,, ,, ...	9th ,,
First back tooth, ...	12th ,,
Eye-teeth, ...	18th ,,
Second back teeth, ...	24th ,,

The first teeth of the lower jaw appear earlier than those of the upper jaw. While the above table gives the average dates, the period varies greatly. Thus the central teeth of the lower jaw may appear as early as the third month, and an interval of some months may then elapse before others are cut. There are cases on record of children being born with some teeth already cut. On the other hand, in some cases the teeth are unusually late of appearing, some remarkable cases being on record of children who cut no teeth till some years after birth. As a rule, if the cutting of the teeth is long delayed, it is an indication of some backwardness of development. It may be due to the child not getting food of a proper quality to supply the needed material for tooth formation, and the slowness of the growth of the teeth may coincide with slowness and softness of bone formation. Parents in such cases should consider whether the child is receiving a sufficiently nourishing diet, and especially should be assured that the diet is not too exclusively of a starchy kind, too much corn-flour, rice, arrowroot, or kindred food, and too little milk, and whether some addition of beef-tea, broth, eggs, &c., should not be made to its diet.

The teeth are already in their sockets in the jaw when the child is born. It is their continuing growth that causes them to press upwards on the gum till they cut through it. While the milk-teeth are pushing their way upwards the foundations of the permanent set are already being laid in the jaws, and when, at the age of two years or two and a half years, all the milk-

teeth are visible, considerable advances have been made in the development of the second set. It is the continued upward growth of the teeth of the permanent set which causes them to press on the roots of those of the milk set. This pressure gradually causes wasting of the roots of the milk-teeth, till, at six years of age, when the first of the permanent set appears above the gum (see pp. 136 and 137), little of some of the milk-teeth is left but the crown attached to the gum, and it usually drops out as the permanent one pushes up to take its place. But at this time, six years of age, the child has not only the twenty milk-teeth, but more deeply in the jaw it has also, already well developed, twenty-eight of the thirty-two that form the permanent set. At this time, therefore, the child has no less than forty-eight teeth in its jaws.

The period of teething is the time when the advancing teeth are pushing up vigorously under the gum, and when the gum is rendered sensitive and painful by the pressure. The pressure is also irritating to other parts, and the excitement carried to the salivary glands (p. 137) by nervous communication causes the constant flow of saliva. The period of teething is, consequently, a time when the child is more than usually irritable and excitable, and more than usually liable to disturbance of various kinds. While this is so, it is too common to blame teething for all sorts of ailments that have little connection with it, and consequently to neglect attending to some of them, or seeking advice for them, in the hope that when the teeth are cut the ailment will pass away. It is the writer's constant experience that, if the mother or nurse will give a little more than ordinary care to the tending and management of the child, and will watch the condition of the bowels, giving, when it seems necessary, a small amount of gently opening medicine, castor-oil or magnesia, and plenty of careful exercise and fresh air, the troubles of teething will cease to alarm and annoy. The various ailments apt to arise during teething and the method of dealing with them, are considered further on in this section. During the period the child is much comforted, and the process of cutting aided, by having a clean india-rubber ring to press and chew with its gums. As a rule lancing the gums is to be avoided.

For the preservation of the permanent teeth children should be trained to use a tooth-brush with warm water daily, using also if need be a tooth-powder of a fine kind. In order to get the child trained to this habit, it is well to teach it to use a brush, even for the milk teeth. A child of two years and a half is quite capable of being trained to a cleanly habit of this sort, and looks upon it as an amusement rather than as an irksome task.

Bathing, Clothing, and Exercise.—The directions already given about bathing infants should be carried out with older children. About six months of age, sluicing with water, which is just tepid, with the morning bath may be given. That is to say, the bath-tub may be filled with water of a moderate warmth, but the child is rapidly sponged with water less warm. Thereafter the drying should be thorough and accompanied by gentle but firm rubbing. If the child seems to feel the cold too much, the colder water should be abandoned for a time. When children become old enough to stand in the bath for the morning cleansing, the water in which they stand should be warm, and tepid water used with a sponge. Children who are able to stand and run about should not be allowed to scamper over the nursery while the bath is being prepared. The body becomes chilled in this way and is unable to stand the cold bath well. The child should be rapidly bathed just out of bed while it is still in full warmth, able to bear the cold and to induce reaction afterwards. At the same time, if it has been unduly warm and sweating in bed, time must be given for it to cool down in bed before being taken to the bath. After bathing the children should be quickly dressed before a fire and then allowed to run about. The evening bath should be always warmer than that of the morning, and from it the child should be put straight to bed. If the practice of the morning cool bath is kept up, then as the child grows it will be so accustomed to it that it will be desired and continued.

Clothing.—Regarding clothing it is only necessary to repeat the objections stated on p. 442 to low-necked short-sleeved dresses, and to socks so short that they do not protect the legs. The dress should fit well, though easily, round the neck, and should always have sleeves to cover the arms. Colds and chest complaints are too frequently due to the half-naked way in which mothers like to see their children's shoulders and arms. If socks are worn, gaiters should be added to protect the legs. When stockings are used, they should never be secured by garters at the knee, for these restrict the circulation and are hurtful; suspenders are the proper means of keeping them up. The same is true of gaiters. Shoes should be as soft and

pliable as possible. Specially while in the house should stiff shoes and boots be removed. They prevent free growth of the muscles of the feet and hinder vigorous and elastic movements.

Exercise.—Up to the age of nine months or thereby a child's exercise is obtained mostly in its nurse's arms, or lying kicking in her lap or in its cot. About nine or ten months, however, the child begins to attempt crawling. If the floor be covered by a warm rug or carpet this is well, but care should be taken that draughts do not sweep across the floor. From crawling it will take to getting on its feet by the aid of a chair and so on till it essays to walk. A mother should let her child go through all the stages at its own sweet will. It will gradually learn itself to use its legs, will become slowly accustomed to maintain the erect position, and thus the muscles are gradually trained to their full use. This is better than setting a child up on its legs and trying to force it into erect ways of moving. If a child is more than usually heavy, its own weight may be too great for the still soft and yielding bones to bear, and the child is often disinclined to attempt standing up straight. It prefers crawling, and it is right, and ought to be allowed to choose its own way.

When children are old enough to walk out and themselves take exercise in the open air, it is best, if there is an open space for it, to let them do so by engaging in some simple game, rather than by dawdling along holding on by the skirts of a nurse. It is free active exercise of arms as well as legs, and of chest muscles too, that a child needs.

During some part of the middle portion of the day the child should have a mid-day sleep, even when it has reached the third or fourth year. In summer the warmest part of the day is best for this purpose, and the room should be cool and darkened, the child being lightly covered. The time of exercise would thus be in the morning before the heat becomes great or in the afternoon, but before it becomes too cool in the evening. In winter the time of the daily sleep needs some alteration to permit the child being out while it is warmest and sunniest.

Children's Apartments.—In houses where the accommodation is sufficient it is well to have a day and a night nursery. Both should be of a moderate size, cheerful and airy, fitted with a fire-place, protected by a guard so efficient that the child can neither crawl through between its bars nor over its top. The ventilation should be well attended to, and should be secured either by a valve ventilator near the roof communicating with the chimney, or by one of the *topmost* panes of the window being perforated, the openings being capable of partial closure. Heated air always rises, and thus impure air, warm from the lungs, rises towards the ceiling and should be allowed a way of escape as high as possible. The arrangement should be such as to avoid draughts. One good method is to raise the lower sash of the windows by a 3-inch board fixed to the sill and on which the sash rests. A space is thus left between the lower and upper sash through which fresh air enters, but it is directed upwards. If possible, the room should not be next door to a bath-room or water-closet; and it should not be in a sunk flat. The windows should be guarded by rods. The rooms should be heated by fires, and not by hot-air pipes or gas-stoves; the communication between the grate and the chimney should never be closed. It ensures ventilation of some kind when open. As soon as the children leave the night nursery in the morning, the windows should be thrown open to let the room be well ventilated; and similarly whenever the opportunity exists by the room being empty, the day nursery should be aired. Further, a nursery should be kept scrupulously clean; all discharges should be quickly removed, as well as dirty linen. No cooking should be done in it, and drying of clothes before the fire should be forbidden. In houses where the accommodation is not sufficient to allow of even one room being used as a nursery, the benefit of the children should be considered, and the principles indicated carried out as far as possible in the other apartments.

THE MANAGEMENT OF CHILDREN IN DISEASE.

GENERAL SIGNS OF DISEASE IN CHILDREN.

Much may be learned as to the state of health of a person by examining the face, eyes, mouth, and various parts of the body; but in dealing with children, who cannot express their feelings, this examination becomes of very great importance. It is possible from it not only to tell whether a child is well or ill, but often also, if ill, what is the character of the ailment and situation of the disease. The information is to be obtained from observing (1) the colour of the skin, face, eyes, lips, (2) the expression of the face and eyes, (3) the state of the mouth and teeth, (4) the gesture and attitude, (5) the movements of the chest, (6) the movements of the

belly, (7) the general state and warmth of the body, (8) the cry of the child, (9) the character of the stools, and (10) the nature of the sleep.

What should be looked for in each of these respects will be briefly indicated.

1. **The Colour of the Skin, Face, Eyes, and Lips.**—The transparent rosy tint of the skin of the healthy child may be replaced by a general *yellow* colour, seen not only over the whole skin, but also in the white of the eye, indicating jaundice, *i.e.* some affection of the *liver*. A form of jaundice is not uncommon in newly-born children (see p. 459). The skin may be dusky, the lips being bluish, and the same duskiness showing strongly under the finger and toe nails. This is associated with a peculiar condition of the *heart* (see BLUE DISEASE, p. 458). In affections of the *lungs*, where the breathing is seriously impeded, a similar alteration of colour affects the face and lips. Serious disease of the *stomach or bowels* produces a *dull, sallow, or leaden* hue of the face.

(2) **Expression and Features.**—The most remarkable and sudden alteration of features is seen in diseases of some part of *the bowel*, where the face is pinched and furrowed, and becomes rapidly emaciated, sunken, and lustreless. The rapid movements of the nostrils, accompanying laboured breathing, is a sign of *affection of the lungs*. Hacks and fissures about the corners of the mouth, sunken bridge of the nose, and a general withered and old-mannish look, are frequent in a disease of the blood called syphilis (p. 422). A large head, with prominent overarching forehead, and small development of the face, is the well-known characteristic of a chronic form of *brain disorder*—water-in-the-head—(p. 101). In the early stage of this trouble the child is drowsy, dull, and listless, however lively and active it may naturally have been. The eyes should be observed as to the way in which they close, the complete or incomplete way in which the eyelids meet, the presence of squinting; and the pupil should be watched to note whether it responds to light—becoming small rapidly when light is directed on the eyes, and again expanding when the light is withdrawn. A wide and fixed pupil is almost certainly a sign of serious *nervous disturbance.*

(3) **Mouth and Teeth.**—The points to notice here are the heat and state of moisture of the mouth, the condition of the gums, the number of the teeth cut or near to cutting, the softness or dryness of the tongue, its colour and cleanness. In teething, of course, the mouth is hot and perhaps dripping with saliva, and the gums may be swollen, tender, and florid. A white tongue points to disorder about the *stomach.* A brown dry tongue is the state in fever of the typhoid type. The tongue is also frequently covered with patches of a white vegetable growth (THRUSH, p. 460). The inside of the lips and cheeks are to be inspected for the presence of small ulcers.

(4) **Gesture and Attitude.**—Note here the movements of the hands and arms. Children, like grown-up people, often try to aid obstructed breathing by grasping with the hands and raising the arms to help expansion of the chest. In severe *fevers* the rigid bend of the fingers with the thumb doubled in on the palm is very noticeable. In irritation of the *bowels* the thighs are bent up on the belly while the pain lasts. The involuntary movements and twitches of *St. Vitus' Dance* (p. 125) are well known.

(5) **Movements of the Chest.**—Rapid and jerky movements, with constriction at the sides, and accompanied by heaving of the belly, and depression at the collar-bones, indicate serious *lung* mischief. Breathing that is accompanied by a pleuritic stitch is manifested by the sudden convulsive stop in the middle of the inspiration, the pain being also shown by the movements of the face and the cry. Disease of the *belly* also affects the movements of the chest, for if movement of the belly causes pain it will be kept quiet, and all the breathing will be performed by chest movements, which will be short and quick, incomplete, that is to say, prevented from going so far as to exert downward pressure on the belly.

(6) **Movement of the Belly.**—As indicated above, the movements of the belly may be exaggerated, when the disease is in the chest, to relieve the chest of the work it is unable to perform, or the movements of the belly may be entirely restrained when it is itself the seat of disease. In the latter case it will be tense, the muscles firmly contracted to guard against movement, and the thighs will be bent up on it to relieve it of strain. When the belly is the seat of pain, specially colicky pain due to flatulence, the contracted muscles make the belly feel tight and firm, and the child usually kicks and twists itself about, crying lustily while the pain lasts. But as soon as the spasm of pain has passed the child speedily quiets down, giving vent only to a final sob or two, unless another attack rouses it to the same crying and kicking. On the other hand, if the pain is inflammatory the child lies moving as little as possible, for movement

increases this pain, and there is moaning rather than crying out.

(7) **The General State and Warmth of the Body** may be gathered from noticing the plumpness or wasted appearance, firmness or softness of the child. The way in which the child holds itself together, also, should be observed, whether bright and buoyant, or languid and drooping. The heat of the body is roughly ascertained by laying the hand on the skin or on the head; but the most reliable means is by using the thermometer (p. 10). It will indicate a rise of temperature amounting to fever when feeling with the hand would give no hint of anything wrong. A mother who learned how to use it, and it is very easy learning its use, would find it of inestimable value. It would not only tell her whether her child was really ill, but also within an hour or two of the employment of her simple method of treatment she would be able to tell by means of it whether any good had been done.

(8) The **cry** of the child is often peculiar. The feeble, plaintive cry is itself sufficiently suggestive. An acute cry, very strong and intermittent, is not infrequent in "water in the head" (p. 101), while a hoarse, muffled cry is heard in croup (p. 417). If a child, apparently healthy, takes suddenly to a constant crying, which movement and dandling seem only to aggravate, thorough search should immediately be made to see that it is not due to some wayward pin, or some uncomfortable fastening or knotting of the dress.

(9) The character of the **stools**, &c., give important indications of the state of the health. In the case of the infant they should be two in number daily, lightish yellow in colour, soft, and not offensive in smell. If they are not so frequent as usual, or more frequent, dark or green coloured, too liquid, or curdy and offensive, something is not quite right, which some slight alteration in the diet, in quantity or quality, or both, may set right even without medicine. (Refer to page 446.)

(10) The **sleep** of children is disturbed during illness. A restless disturbed sleep, from which the child often starts up with a cry, should always call attention to the child's state of health. It may be only some error in diet that is the cause. If so, this will be indicated by the state of the stools. Perhaps the child has had no motion the previous day. Let inquiry be made, and opening medicine given if necessary. Disturbance in the bowels due to worms is a frequent cause of this restlessness (p. 463). On the other hand, an undue drowsiness, languor, and listlessness are not to be neglected, specially in children between two and seven years of age. These are among the early signs of brain disease.

GENERAL TREATMENT OF CHILDREN IN DISEASE.

When a child is suspected or seen to be unwell there are certain steps that ought to be taken at once, no matter what may be the nature of the illness, steps which, if taken immediately, will, in many cases, be able to convert into a short and slight illness what, if neglected, might become a long and serious one, and which may even be sufficient to arrest the illness altogether. As soon as the child is supposed to be ill it should be stripped, bathed, and put to bed, if possible in a quiet room, not in a noisy, much-frequented apartment. The bed should be fresh and clean, not closed in, and freed entirely from hangings and curtains. *The room should be well ventilated, but free from draughts.* A fire secures a continuous supply of good air to a considerable extent, besides warming the room, which should be kept as much as possible at a regular temperature—a moderate one (62° Fahrenheit)—which is most easily managed by the aid of a thermometer kept hanging in the room. At once attention is to be directed to (1) the diet of the child and (2) the state of the bowels. (1) The whole trouble may have arisen from overfeeding or improper feeding. The child is, therefore, to be put on milk diet mainly, to which, if its age warrants it, light beef-tea or broth (strained) may be added (see the directions given under MANAGEMENT OF CHILDREN, p. 449). The quantity is to be kept strictly moderate, small quantities given in frequent but regular intervals being better than large quantities at one time. Irregular feeding must be avoided, and no solid animal food whatever given. (2) If the bowels have not been properly moved for some time a moderate dose of castor-oil or of fluid magnesia, or similar mild purgative, may be given. This is, generally speaking, all that should be done on the mother's or nurse's sole responsibility, when the services of a medical man are at all obtainable. When such services can be obtained they should be at once sent for, as very slight symptoms may be the forerunners of very serious disease. The medical man being in attendance his advice, *and none other*, should be strictly, promptly, and conscientiously followed.

But it will often happen that medical aid is not within immediate reach; that, owing to distance or some other case, it may be many hours before the doctor can arrive. Meanwhile the child seems highly fevered, is very restless in its sleep, seems to be wandering, or the mother fears convulsions. What is to be done? This, at any rate, must not be done: the mother or nurse must not seek to quiet the child by "soothing syrups" of any description. Especially in nervous conditions is a great deal of harm possible by their means. There are, however, two things the mother may do without the least fear, two things beside what has been already advised. First an injection into the bowel should be given for the purpose of producing at once a full clearing out of the lower bowel. The fact that castor-oil or some other opening medicine has been already given does not stand in the way of the injection, if it seems needed, for the injection will clear out the lower part of the bowel, while the medicine sweeps everything down from the upper end.

Mode of Injection.—An enema-syringe should be used (see plate of Nursery Appliances). It is an oval elastic bag, with an opening at each end of the oval; from each opening proceeds an elastic tube. One tube ends in a long ivory nozzle for insertion into the bowel. The other end dips into a bowl of water. When the bag is compressed by the hand anything it contains is forced out through the nozzle; when it is allowed to expand it sucks up a fresh supply of water by the other tube, the movement of the water being directed by valves. Take a small bowl of tepid water, work the syringe for a little time till it is found to be in good working order, expelling a steady stream of water, unmixed with air, from the nozzle with each compression of the bag. Now oil the nozzle, and by a twisting movement gently pass it up into the child's bowel, using no force, and directing the point slightly backwards and to the left, the child lying on its left side in bed or in the nurse's lap. An ivory plate prevents it being pushed too far. Then gently but steadily squeeze the bag till the water has all passed into the bowel, then relax and let it refill, gently press again. *Take care that all the time the other tube—the inlet tube—is dipping below the surface of the water in the bowl, so that no air is sucked in.* Even in the case of quite a young child the quantity injected by two or three compressions of the bag is not too much, when it is desired to act well and quickly. With older children a small bowlful of water may be injected with perfect safety. Besides plain water, soapy water and salt and water are often used, one table-spoonful of salt to half a pint of water. The salt and water act quickly and energetically. When an enema-syringe cannot be obtained, a brass one with ivory point may be used. Glass syringes are rather to be avoided, and, if used, great care must be taken that the point is quite round and not sharp, and that it is not broken in the bowel.

The second thing that may be done for a child threatened with some illness that looks serious is to give it a special warm bath or wrap it in a warm pack.

To give **the warm bath** the water should be at a temperature of 98° Fahr., and it is best to test the heat by the thermometer rather than by feeling with the hand. The child should be set in the bath up to the neck, and a blanket fastened round the neck of the child, and sweeping round the sides of the bath should completely envelop bath and child. The child should remain in the bath for twenty minutes to half an hour, the heat being all the time maintained by frequent additions of warm water round the sides. The child may then be lifted up, rolled in the blanket already round its neck, and without any drying put into bed. After another hour, or even less if the child finds the blanket too disagreeable to let it rest, the child should be rapidly rubbed down, clothed in a warm flannel gown and carefully wrapped in the bed-clothes. Or the child may at once, on being lifted from the bath, be rubbed down, clothed in flannel and put to bed.

The warm pack.—The child is to be stripped naked and rolled in a half-sheet or half-blanket wrung lightly out of warm water. It should be kept so for an hour and then rubbed down, and its flannel night-gown put on. Young children grow restless by being imprisoned in the wet sheet. They are usually quiet if their arms are allowed out.

The benefit of the warm bath is that it brings the blood to the skin, it causes the blood-vessels of the skin to relax. They become able to contain more blood in consequence, and thus deeper parts are relieved of too great a quantity of blood. At the same time, if there is fever, the water used being of a considerably less degree of heat than the blood, heat is withdrawn from the body, and that has a soothing effect on the nervous system. If, as has been advised, an injection has previously been given and has produced free evacuations, the unloading of the bowels will have already acted in a similar way.

The blood will have been diverted from the head and central nervous system, and the calming effect of the bath or hot pack will be all the more perceptible because of this previous action.

Now these two methods of treatment of children are simple in the extreme, and if carried out with a moderate degree of intelligence are incapable of doing harm. They will often dispel from the child within a short time all the more alarming symptoms, and secure for it some quiet rest and sleep. Often a child, that late in the evening shows signs of some serious illness, if treated in this way, and if care is given to the diet, &c., as already directed, will appear perfectly well in the morning. Even if not, and even if the illness does go on, the child is in a much more favourable condition in relation to the future course of the illness than it would have been.

AFFECTIONS OF THE NEWLY-BORN CHILD.

Irregularities of Form in the Newly-born.

An irregularly shaped head is not infrequent as the result of severe labour, or the use of instruments, &c. It is frequently extremely elongated, perhaps badly flattened or pressed in at one side. No fear is to be entertained on this account. Within a few days the head will gradually return to the normal shape.

Tumours or swellings may exist on the back of the head or at other parts of the head. **Spina Bifida** is the name given to a tumour occurring at the lower end of the backbone, due to an arrest of the growth of the bone, and protrusion of the membranes and other parts of the spinal cord in the shape of a bag. It is in many cases amenable to skilled treatment. Such swellings must not be interfered with by the mother or nurse. They are carefully to be guarded from injury or pressure. Spina bifida is much less serious than the similar condition of the head, and children born with it may be otherwise well-formed and healthy. A pad should be carefully adjusted and fixed over the swelling so as to maintain all over it a moderate degree of pressure.

Defects in the Opening of the Bowel or Urinary Passages sometimes exist. They should at once be brought under the notice of the medical attendant.

Hare-lip.—Hare-lip or split-lip occurs on the upper lip, the split being on one side of the middle line or the other, or on both sides. It is due to an arrest of development. For the upper jaw is formed by parts from each side growing inwards towards the middle line. They do not meet in the middle, but in the gap left growth takes place of an intermediate part which in time unites completely with the parts on each side, and thus the complete upper jaw is formed. This intermediate part it is which in the developed condition carries the four front teeth. Now hare-lip is an arrest of the growth at one period or another, the result of which is that complete union is not effected at one or other side or at both. The split may involve the soft parts only, or it may extend through to the bone. In the most extreme cases the central part of the upper jaw, including the bone and soft parts connected with it, is quite ununited with the rest of the upper jaw at each side. Often this central portion is projected forwards and upwards, standing straight out from the face, and sometimes it is so much twisted to one side as to block one nostril, out of which it seems to be sticking. In such cases the palate is cleft also, that is, the roof of the mouth is deficient in the middle line, owing to an arrest in the development of the bone, which should have grown forward till junction and complete union was effected in the middle line.

Cleft-palate in slight cases only involves the soft parts at the back of the mouth, the uvula, &c. (Fig. 136, p. 263). As it extends forward it involves the bone, till in extreme cases the cleft passes from back to front. There is thus no separation between the cavities of the mouth and nostrils.

When hare-lip exists alone, bone union being complete, the deformity is the only thing, and it can easily be remedied by an operation, which will leave little or no hint of the original condition. But when it is associated with non-union of the bone it interferes with suckling. This may sometimes be remedied by the mother using a nipple shield with a large nipple. When, however, the split is large and cleft-palate also exists, suckling is impossible, and even feeding is very difficult. Cleft-palate may exist alone to a greater or less extent. In many cases it is not noticeable till the child begins to speak, and then it is recognized by the peculiar nasal "twang." Both conditions can be remedied by operations. For hare-lip the operation should be performed before teething. It is not attended by danger, and its results in improving the appearance are remarkable. For cleft-palate there

is no haste, but it should not be delayed till the child has learned to speak and has acquired the "twang." It is not nearly so simple an operation as the former. In extreme cases the separation may be too great to permit of closure by operation, but a plate may be made to cover the opening.

Blue Disease (*Cyanosis*) is due to an arrest of development interfering with proper aeration of the blood. While the child is still in the womb its own lungs are inactive and unexpanded. The aeration of the blood of the child is effected indirectly through the blood of the mother. The blood of the child passes in the vessels of the cord to the placenta, which connects the child to the mother, and is there purified by exchanges with the blood of the mother. Returning from the placenta the blood of the child passes to the upper chamber of the right side of the heart, partly directly and partly through the liver. In the adult the right and left sides of the heart are separated by a complete partition, but in the fœtus an opening exists through which the pure blood can pass directly through the right upper chamber to the left, and from the left side it is then distributed through the body. After birth this opening should close, and then the blood requires to pass from the right side through the lungs, where it is purified, before it reaches the left. In rare cases this opening remains unclosed, and thus while part of the blood passes through the lungs to the left side, part escapes directly from right to left without previously passing through the lungs, and thus without aeration. The blood is, therefore, constantly deficient in oxygen, and the blueness arises in consequence. The child's skin, its cheeks, lips, hands, and feet are markedly livid, the fingers and toes are clubbed and the nails are incurved. It breathes rapidly and is liable to attacks of breathlessness. In marked cases death usually occurs in a few days, in slighter cases life may be prolonged for some years. All that can be done is to keep the child quiet and to protect from cold.

Tongue-tied. — This condition is due to shortening of the bridle of the tongue. When it is present the child cannot push the tongue out over the lips; and it interferes with the suckling. It is easily set right by turning up the tongue and dividing the front of the bridle by means of a blunt-pointed pair of scissors. This should only be done by a medical man, for if the scissors be directed upwards one of the blood-vessels running along the under surface of the tongue may be injured.

Cataract. — Children are sometimes born with white spots in the lens of the eye, interfering with sight, or the whole lens may be white, rendering seeing impossible. This is due to some defect of nourishment in the womb. The child should be taken early to an oculist, as an operation is frequently necessary very early to prevent changes arising in the eye that would interfere with the usefulness of an operation at a later period. (See p. 374.)

Diseases of the Newly-born.

Ulceration or Bleeding at the Navel.—If the bleeding be from the attached piece of cord it should be tied a second time nearer the belly. This may occur some hours after birth because the cord has been improperly tied. The clothing should be immediately undone and the cord tied again between the former place and the belly. Four or six strands of linen thread form the best material for the purpose. It may also occur owing to the remains of the cord being too early separated. If so, the bleeding is best stopped by gentle steady pressure with the finger or a small pad. It should not be allowed to continue, else the slow drain may be very hurtful. If the part be not healing properly, it should be carefully sponged frequently, and if necessary may be painted with an astringent like syrup of tannin, or tannate of glycerine.

Inflammation of the Eyes.—One form of inflammation of the eyes of a newly-born child, if not watched with great care, may ruin the child's eyes in the course of a few days, and render the infant incurably blind. It begins usually about the third or fourth day after birth. The eyelashes stick together, and the borders of the lids are red and crusted. Both eyes are attacked, the one after the other. The lids become swollen, and in a day or two thin fluid pours out of the eyes, the fluid in about a week has changed to matter, with which the eyes are constantly overflowing. The treatment consists in keeping the eyes scrupulously and constantly clean. Use warm water, and a soft rag or lint: *open the eyes thoroughly, turning out the lids, and cleaning away every particle of matter.* To the warm water a few drops of Condy's fluid, sufficient to make the water slightly pink, may be added. *This must be done*

not once nor twice daily but very often, so that no matter is allowed to accumulate in the eye. No ointments should be used. The inflammation, however, is of so dangerous a character in its effects upon the sight, that no time should be lost in having proper medical treatment.

Jaundice.—This is not uncommon during the first or second week of infant life, the skin and white of the eyes becoming quite yellow, and the stools colourless. It is not to be feared. Usually no remedies are required. It will pass off often as quickly as it came. If excessive give a small dose of castor-oil only.

Swelling of the Breasts.—This is not infrequent in newly-born children. The breasts are firm and tense, and occasionally fluid like milk oozes from them. *They should not be squeezed or pressed in any way.* Gentle rubbing with warm oil is often all that is necessary. Where redness or a purplish tinge indicates a more severe form of swelling, a soothing poultice of warm bread and water should be applied, or a warm sponge held on them each time the child is bathed.

Retention of Urine and Stools.—This may be caused by some defect already alluded to (p. 457). The nurse is never, by any means, to give "nitre" in the hope of causing the child to make water. She may use a warm bath, or place warm cloths over the lower part of the belly, and that usually will be sufficient. The attention of the medical attendant should be directed to the child if this is insufficient.

Moles and Mother's Marks.—These have been sufficiently considered on pages 247 and 322.

DISEASES COMMON TO CHILDHOOD.

Ailments at the Periods of Teething and Weaning.

The period of teething is undoubtedly a time when the child is easily upset, restless and highly excitable, and, therefore, more liable to ailments than at other times. But it is quite certain that to the teething process is attributed all sorts of trouble, due rather to careless nursing and bad management. In some cases the child is dosed with medicines of one kind or another, in other cases the excuse, "Oh! it is just the teeth," is given for every disturbance of health; and without much further thought the mother or nurse waits on time to remedy the ailment, when the teeth will all have been cut. Both methods are mistaken. It is not to be forgotten that the child is at a stage of development when it is in a peculiarly sensitive condition, but just for this reason more watchful care is to be exercised, and while medicines are avoided more attention is to be paid to good management. Disturbances of stomach and bowels are common, looseness of bowels especially. These are to be met by careful nursing and dieting, as indicated on p. 460. The same careful management will diminish the restlessness and excitability of the child. If, however, the bowels being free and regular, the child is much disturbed, mothers often feel they must give something to calm and soothe. Again it is necessary to repeat the warning against so-called soothing syrups, given on p. 447. One drug, however, may be given to calm the nervous system, and it is devoid of danger. It is bromide of potassium. Let 32 grains be dissolved in a little water and made up to one ounce, that is eight tea-spoonfuls, with simple syrup. Of this a tea-spoonful is given occasionally, but not frequently repeated. Lancing the gums, so often resorted to, is as a rule a barbarous practice, and is never done by modern physicians, unless the gum over the coming tooth is distinctly red and angry looking, and the tooth near the surface.

Inflammation of the gums does justify the procedure, and is greatly relieved by it, and that even though the tooth be not yet near the surface. The inflammation is readily known by the swollen state of the gum, and its dark-red appearance. In such a case, when the tooth is yet deep in the gum, the lance should be applied to the side and not over the coming tooth. For if the wound heal before the tooth is cut the scar is likely to make the cutting of the tooth more difficult.

At the period of weaning disorder of stomach and bowels is frequent. This difficulty may also be overcome by management. If the child's bowels are very troublesome, the mother had better delay the process for a little and then try again, or effect it very slowly.

Coughs, Colds, and Affections of the Chest.

Cold may take the form of running at the nose—**snuffles**—(preceded by frequent sneezing), watery eyes, some degree of feverishness, and the child is cross. This is a form of what is called "catarrh," from two Greek words

meaning "a running down" (see p. 154). It may extend from the nose to the throat, causing it to become red and swollen, may pass down into the windpipe, and may also cause a similar condition in the stomach, called catarrh of the stomach. In these severer forms there will be loss of appetite, white tongue, and if the child can speak it may complain of headache and pains in the back or limbs. Whether the attack be mild or severe, simple treatment is all that is required, that is, give the child a warm bath, keep it warm in bed, give gentle opening medicine—castor-oil—at once, let it be fed on slops, and give thrice or so daily 5 to 10 drops ipecacuanha wine. If the nose is very much obstructed some relief may be given by laying over it a sponge squeezed out of hot water. This is all the treatment that should be adopted without medical advice. This affection may, however, go on, the lungs may become affected and bronchitis or other disease of the chest result.

Bronchitis (p. 270).—This will be attended with quick, hurried breathing, with flushed face, and other aggravated signs. The ear applied to some part of the chest may detect wheezing or piping sounds. These are too serious forms of disease to be delayed over, and medical aid should speedily be secured. The treament advised on p. 271 may be adopted for children to the extent of applying a hot poultice occasionally to the affected side of the chest, and using the bronchitis-kettle, a constant stream of steam being poured in the neighbourhood of the child's cot.

Cough is present in most of the above affections, and is to be treated as described for cold. But, not infrequently, especially when the back part of the throat is evidently red and congested, the cough may be very irritating and even suffocative. This is often relieved, in addition to the means already mentioned, by putting a small, mild, hot poultice on the front of the neck, just over "Adam's apple," and giving repeated small doses of ipecacuanha wine, and if necessary by using the steam from a kettle as noted above.

There is a cough, however, which should rouse instant intention, a hoarse muffled cough "like the distant bark of a puppy," or a cough with a ringing metallic sound—a brassy cough. Let the mother or nurse be on guard against croup, of which this is strongly suspicious. (See p. 418.)

Affections of the Mouth, Stomach, and Bowels.

Thrush.—In this disease the tongue and inside of the mouth are covered by white patches of a peculiar growth, sometimes forming a continuous white crust. It is often accompanied by disordered stomach and bowels, particularly if the child be weakly. The patches are really due to the growth of a minute microscopic plant, flourishing because of the unhealthy state of the digestive canal.

Treatment. (1) Give mild opening medicine —magnesia with a little rhubarb. (2) Correct at once any errors in diet. (3) Apply to the mouth borax and honey, or glycerine with an equal part of solution of borax, or chlorate of potash (20 to 30 grains of either to an ounce of water). The disease will not be properly cured unless the disordered stomach is set right by proper dieting.

Ulcers on Lips and different parts of the mouth occur readily in children whose stomach and bowels are in bad condition. Treatment is the same as for thrush.

Inflammation of the Mouth of an extremely serious kind is seen in weakly, ill-fed children, living in large towns, in badly-aired apartments. It frequently follows on measles or other weakening disease. It begins as an ulcer, of a dirty ash-gray colour, on the lip or inside of the cheek, and eats its way into the cheek and gums. The face is swollen, saliva dribbles from the mouth, the breath is foul-smelling, and the teeth may drop out. The pulse fails, the stomach and bowels become disordered, and death results, often very rapidly, from exhaustion.

Treatment requires first of all to be directed to cleanse the stomach and bowels by a dose of rhubarb and magnesia. Nourishing food must be freely supplied, but in small quantities given often, milk and beef-tea specially. Wine is frequently needed to combat the feebleness. A mixture of chlorate of potash, 60 grains, syrup, 1 ounce, and water, 3 ounces, should be obtained, of which one to two tea-spoonfuls should be given every four hours. The mouth should be bathed with a solution of 30 grains chlorate of potash to 1 ounce of water.

Derangements of the Stomach and Bowels.—These are oftenest due to improper feeding; they also are frequent at periods like teething, weaning, and so on. They may be due to excessive quantity of the milk or altered

quality. If the child be at the breast it may have been too frequently suckled, or owing to some condition of the mother, or some improper food taken by her, the quality of her milk has been changed. This can be easily remedied. If the child is not at the breast the quantity and kind of food it is getting must be seen to. Similarly too sudden weaning, or irritation due to teething, may be the cause. If the cause can be discovered let it be removed at once, and probably, without further steps, but simply under the influence of proper food, given at proper intervals and in the right quantity, the child will be restored.

Vomiting is one sign of stomach derangement. If the child vomits the milk, unchanged, soon after taking it, and is immediately well and cheerful, *it has had too much.* Therefore let the quantity and frequency of suckling be diminished. Or if the child vomits frequently and looks pale and exhausted, is fretful and whining, and never easy unless when at the breast, sucking greedily and never satisfied, here again there is indigestion, caused also probably by improper dieting. If regulating the feeding in the ordinary way (p. 441) does not allay the irritability of the stomach, stop altogether giving the ordinary quantities, and give very small quantities of milk—one or two tea-spoonfuls—at intervals of twenty minutes or half an hour, for a considerable number of hours, or till the vomiting ceases. Then gradually increase the quantity and lengthen the intervals, till ordinary quantities are given every three or four hours. A warm poultice over the stomach will also help. Vomiting, persistent no matter what or how little is taken, occurs in disorder of the stomach from cold. If the plan already advised, one or two tea-spoonfuls at a time and at brief intervals, and warm applications over the belly, does not arrest it, then let some ice be obtained. A few pieces should be put into a glass of fresh milk, and the whole allowed to stand till the milk is ice-cold. Of this give the child a tea-spoonful, or at the most two every half-hour or so, and apply warmth outside. After the lapse of some hours give the iced milk less frequently, and give one or two tea-spoonfuls of ordinary milk between the doses. The irritability will almost certainly yield to this method, and gradually larger quantities of ordinary milk at longer intervals may be given. *It is needful to avoid giving any considerable quantity of the iced milk at a time, for that would be hurtful.*

Colic and Flatulence are manifested by the infant suddenly becoming fretful. It draws up its legs towards the belly and cries for a time, and then returns to its usual state. This is repeated on another attack. The distress may be great and the pain long, shown by the long-continued screaming and violent movements of the legs, and it may be relieved by a discharge of wind or stools. Here, again, look to the food the child is receiving. Get rid of any irritating matter by giving a dose of castor-oil, after which magnesia in doses of 3 to 5 grains, or fluid magnesia, one to two dessert-spoonfuls, may be given occasionally if required. When the colic is present rubbing the belly with the warm hand, or applying hot cloths will relieve it. The only other remedy that the mother or nurse should use is dill-water, of which half to one tea-spoonful is sufficient, or essence of anise, 5 drops on sugar.

Diarrhœa.—This may be of a simple kind in which merely the number of motions is increased. Such looseness is often the result of the irritation of teething, or the result of weaning, and is not to be regarded with alarm, though it is to be watched. Changing the diet entirely will often suffice to stop it. Thus instead of cow's milk give goats' or asses' milk, or condensed milk; or, if this does not succeed, stop milk entirely and give thin arrowroot made with water, weak chicken or mutton broth, &c. Frequently the addition of lime-water to the milk (a table-spoonful or so to a cupful of milk) may check the diarrhœa, or 5 drops of ipecacuanha wine in a tea-spoonful of dill-water every hour or two if the looseness is continuous. *Laudanum should on no account be given by a mother or nurse.* Even a single drop has been the cause of a child's death. As regards beef-tea and broths it is to be noticed that if given strong and in any quantity they rather encourage the looseness. Therefore let them be given weak and in small quantities at a time; and further to check the tendency to increase the looseness it is well to boil the beef-tea or broth with sufficient corn-flour to thicken it slightly. Besides the simple form of diarrhœa there are others in which the motions are greenish, slimy and offensive, and passed with straining, accompanied by great pain and exhaustion, the purging being attended by vomiting.

Looseness due to an inflammatory condition of the digestive tract, an **intestinal catarrh** (see p. 162), is attended by symptoms of this kind.

Infantile cholera or summer diarrhœa of children is also of this description. It usually begins suddenly with vomiting of milk little changed and with the passage from the bowel of greenish-yellow material, flaky, and containing lumps of undigested food. The child is restless, pained, as evidenced by the movements of the legs, and cries for and greedily drinks water. The motions become watery and colourless, and so much fluid is passed from the body in a short time that the child becomes excessively exhausted, with pinched dusky face and hollow eyes. This is a very dangerous kind, for the child may die exhausted in a comparatively short time. No delay in getting medical advice should be suffered in such severe forms. Till this can be got the ordinary diet should be stopped. The child should have plenty of cold water to drink, and should be permitted to suck small pieces of ice. The belly should in all cases be kept warm, and much may be done by rubbing or applying warm cloths, or a hot poultice made of equal parts of mustard and flour should be applied over the belly. At the outset it is well to give a single dose of castor-oil to clear away any irritating material. The following mixture may then be used:—

Aromatic Spirit of Ammonia...quarter of an ounce.
Ipecacuanha Wine................50 drops.
Subnitrate of Bismuth...........24 grains.
Mucilage and Syrup, of each...1 ounce.

Mix, and give a tea-spoonful every two hours as required.

White of egg beat up in water and slightly sweetened may also be given to drink. To meet exhaustion 5 to 15 drops of brandy in water may be given every half-hour or hour as seems necessary. It is exceedingly dangerous to give laudanum in such cases, and as a rule it should be given only by the medical man himself. If, however, the case is urgent, and medical advice not obtainable at the time, *a single drop* may be added to the brandy and water if the child is a year old or nearly so. This may be repeated in two or three hours if deemed necessary, but not a third time without advice. Should the child fall into a natural sleep it is probably a good sign. When the acute stage is passed, milk should be given in small quantities, to which lime-water has been added, and the milk should first be boiled.

Chronic diarrhœa, which occurs between weaning and the end of teething, is best met by the use of raw beef if the changes in diet advised at the beginning of this article are not sufficient. The beef is scraped into a pulp and mixed with salt, sugar, or fruit-jelly, and rolled into little balls or given as a sort of paste. Small quantities are given at first, and gradually increased till a child may take a quarter of a pound of meat so prepared daily. The only drink allowed is white of egg in sweetened water. After a time the ordinary diet may be gradually restored. To avoid the danger of worms the best meat should be obtained.

Intestinal Obstruction as it occurs in children is in the form of **intussusception,** in which one part of the bowel slips into another part, as one part of the finger of a glove may be made to slip into the neighbouring part. It is met with in infancy and early childhood, the male child being more liable to it than the female. It is occasioned by irregular action of the bowels, sometimes set up by improper food, by the presence of worms, or by diarrhœa. It is very liable to be misunderstood, the illness being taken for an attack of colic or diarrhœa, for though proper motions are not passed, a bloody discharge is.

The **symptoms** arise suddenly with very severe pain, readily causing convulsions. Vomiting soon occurs, and the *vomit is often streaked with blood, and in a short time becomes smelling of fœcal matters.* Severe straining at stool is present, and a bloody discharge is passed without proper motions. On examining the belly the mass of obstructed bowel may be detected as a sausage-like swelling. The child may die in a few days of shock or exhaustion.

The **treatment** must be prompt. Vomiting of material from the bowel and the discharge of blood should lead to help being instantly obtained. *Purgative medicines do harm.* The mother or nurse may, by means of an enema syringe, inject into the bowel, slowly and carefully, thin gruel or thin starch. This may be done in large quantity in the hope of releasing the obstruction by filling the bowel, and so causing it to slip up out of its unnatural position.

Costiveness.—It must be noticed that some children are costive by habit, and have motion only once in two or three days. It must also be remembered that frequent dosing with medicine is itself productive of costiveness, and is otherwise injurious. Medicines should therefore be avoided as much as possible, and reliance placed on proper dieting and on training the child to regular habits, to train it to seek relief at, as nearly as possible, the same time every

day, say after breakfast. Changing the diet is often as valuable for costiveness as for diarrhœa. When some form of medicine is necessary castor-oil or manna may be used. A simple treatment is to cut a piece of yellow soap into the shape and half the length of the little finger and push it gently up for 2 or 3 inches into the bowel, and there allow it to remain till it excites the motion. If two or three days have been allowed to pass without the child securing a motion it may be necessary to inject one or two syringe-fuls of tepid water as directed on p. 456. When castor-oil is given for costiveness it is well, instead of giving it now and then, to give a small quantity at the same time each morning for a good number of days, and when the bowels are regular the quantity should be gradually diminished till finally it is stopped altogether.

Worms.—These may often be prevented by the careful avoidance of improper kinds of food, and by proper seasoning of the food with salt. They are often introduced with animal food. Great care should, therefore, be exercised in the thorough cooking of all butcher-meat, especially pork, ham, and sausages. They are of three kinds —(1) Tape-worm passed in pieces like flat white tape, (2) round-worm, and (3) thread-worm. They, and all the symptoms they produce, have been sufficiently described on p. 167 and following pages. It is specially thread-worms that affect children. The best treatment is 1 to 3 grains of santonin given in the morning in cream, and some hours afterwards repeated injections of tepid water, in every half-pint of which a table-spoonful of salt has been dissolved, serve to bring them away. Steel-wine or a tonic of some kind should thereafter be given to the child, as well as good food, as debility favours the presence of worms. For the method of injection see p. 456.

Falling of the Bowel. — This may arise from debility, from diarrhœa, or from costiveness owing to straining. It is to be prevented by getting the child into a proper state of health, relieving the costiveness, or checking the diarrhœa. *The bowel must not be allowed to remain down.* To return it bathe the part gently with cold water, form the fingers into a cone and embracing the part gently push it upwards.

Rupture. —This may occur at the navel within a month or two after the child's birth. It is a swelling which increases with crying or straining. It is caused by a portion of the bowel being forced through the little opening at the navel under the skin. The bowel must be kept within the belly by a small firm pad, secured by a bandage. Rupture in the groin shows a swelling in one or other groin passing downwards and inwards to between the legs. It may exist at birth or be brought on by straining, coughing, or crying. The bowel should be returned at once into the belly, and a proper truss obtained for keeping it constantly in place.

Bed-wetting (*Incontinence of Urine*).—This is a frequent affection, and is due very often to the presence of some irritant in the bowels, such as worms, or about the private parts. Careful search should, therefore, be made for such a cause. Attention should be given to the diet to avoid an irritating quality of the urine. Only simple food should be given, pastries and such things being avoided, and simple drink also, milk or water. Before going to bed each night the child should be set down in a warm salt-water bath, covered with a blanket, for 10 to 20 minutes, and should be roused several times during the night to empty the bladder. It is also recommended that the child should be prevented sleeping on its back by some simple contrivance, such as binding on a thread bobbin. If these measures fail, a doctor should be speedily consulted, lest the habit become confirmed. Mothers should be careful that children are not punished for what may be a weakness rather than a fault. If a doctor is not easily obtainable, let the child get 2 to 4 drops of tincture of belladonna in a little water before going to bed.

Spasmodic and Nervous Diseases.

Convulsions may be due to disordered stomach and bowels, caused, for instance, by too much food, or by improper food (unripe fruit, raw carrots, turnips, &c.). They may be due to teething, constipation, worms; they occur sometimes at the beginning, or during the course, of some diseases, such as scarlet fever, &c., and they are frequent in diseases of the brain, such as "water in the head." They may be slight or severe, from mere twitching of face to those accompanied by staring eyes, distorted features, and violently agitated or rigid limbs. Convulsions are readily caused in children because of the nervous matter of the spinal cord being very excitable in them, owing to the controlling action of the brain being not yet well developed. Any irritation, therefore, conveyed to the spinal cord is readily communicated to nerves passing to various groups of muscles, and a stimulus is

thus quickly conveyed to the muscles causing them to pass into a state of rapid contraction. Now the commonest irritation is that derived from the bowels because of the presence of some undesirable material, improper food, or undigested masses of food for example.

The period of teething is also an age liable to convulsions, not only because of the constant irritation, but also because at the time the child's nervous system is in a highly excitable condition. The treatment is twofold (*a*) during the attack, and (*b*) preventive. (*a*) Loosen the child's clothing: dash cold water in its face, or on the chest. A mere sprinkling of water is of no use: a good quantity should be thrown straight on the child. Immerse the child up to the belly in a warm bath, and apply cold to the head. If the cause is suspected to be in the stomach give a dose of ipecacuanha wine to cause vomiting, from a tea-spoonful upwards according to age: if in the bowels give an injection according to directions given in p. 456. In any case an injection is most valuable. Salt water may be used for the injection, or soap and water, or castor-oil and warm water. (*b*) Correct errors in diet: if the gums are highly inflamed and seem to be the cause, lancing will relieve them. Frequently convulsions indicate very serious brain mischief, and therefore the advisability of at all times consulting a doctor.

Night-terrors, in which a child starts up from sleep shrieking and in a state of extreme terror, are commonly caused by irritation through undigested or indigestible food. Care in the management of food, already so often advised, and attention to the bowels, will prevent their recurrence.

Spasm at the head of the Windpipe—Child-crowing—False Croup.—The child is suddenly seized, and frequently during sleep, with spasm that prevents the entrance of air to the lungs; the face becomes swollen, red, and then bluish, owing to the great difficulty of breathing. The child is extremely agitated, and there seems a tendency to convulsions. In a short time the spasm yields, the air rushes in with a long crowing noise, and the child falls back pale and exhausted, and becomes in a short time composed as if nothing had happened. The fit may recur and may, if prolonged, cause death by suffocation. It is a nervous disease, and occurs owing to nervous irritability. The irritation may be from teething, or the child may be so excitable that a slight fright may occasion it. Use cold water as recommended in convulsions, and allow plenty of fresh air. A hot foot-bath with mustard, or a warm bath for the whole body is also useful. While the child is in the fit, forcibly open the mouth and pull forward the tongue, grasping it by a handkerchief between fingers and thumb. As a preventive, bromide of potassium, in doses from 2 to 5 grains, with 5 drops spirits of ether or tincture of valerian is useful. Examine the teeth and watch the bowels, so that any cause of irritation may be removed.

St. Vitus' Dance or Chorea is discussed on p. 125.

Water-in-the-Head is considered on pp. 101 and 102.

Paralysis as it sometimes attacks children is discussed on p. 122.

Fevers and other Infectious Diseases.

These have already been discussed elsewhere.

Scrofula and Consumption.

Refer to pages 431 and 282.

Mothers who are concerned about the delicacy of some child should take special pains in guarding and rearing it, after the manner suggested on pages 282 and 431.

Skin Diseases.

Skin diseases have been sufficiently discussed in Section XI., page 311 and following pages. In general they are to be treated by dieting, attention to the bowels, and frequent use of the bath and carbolic-acid or tar soap.

Nettle-rash.—See p. 314.

Red-gum Rash.—See Lichen, p. 319.

Tooth-rash is similar to the above, and to be treated in the same way.

Scalled-head. See Eczema, p. 318.—It may, however, be noted here regarding this skin affection that it is attended by the formation of "watery heads," which leak, are very itchy,

and give rise to yellowish-green scabs. It occurs often on the head, ears, nose, &c. The scabs should be got rid of by warm poultices of soft mashed turnips. Bathing with warm water to which a pinch of soda has been added will relieve the itching. When the scabs have been *completely* removed, the ointment mentioned on p. 319 should be used; or better still a new ointment called chrisma sulphur. The child's system should be strengthened by cod-liver oil, chemical food, &c.

Running Ears should be treated by gently syringing the ears twice or thrice daily with lukewarm water (see p. 382).

Rickets.

Refer to p. 30.

Bow-legs are to be prevented by treatment similar to that for rickets.

Accidents.

Scalds and Burns.—Remove the clothing as carefully as possible. Put the child in bed and see that it is warm. Arrange a box, wire-guard, or other similar contrivance over the burned part to keep off contact with bed-clothes. Under such an arrangement the injured part is to be kept free from cloths, cotton or other material, while at the same time kept warm. Paint the part, by means of a feather, with a mixture of equal parts of raw linseed-oil and lime-water. This is very cool and soothing if freely and frequently applied. In every house a bottle of this mixture should be kept, and quickly painted on the slightest burn or scald. Should a child's clothing take fire, throw over it a shawl, blanket, or other woollen article, and so smother out the fire. If the mouth or throat have been severely scalded, let ice be sucked till medical aid is obtained.

Wounds and Bruises.—If the wound is clean cut, bathe with cold water. This, with gentle but firm pressure, will stop bleeding. Remove any dirt or other foreign matter; bring the edges together accurately and keep them there with plaster and a bandage. To bruises apply cold-water cloths *if it is attended to at once.* This prevents swelling of the part. Any swelling, blueness, &c., which may result can afterwards be got rid of by aid of warm-water cloths. For wounds and bruises a recent remedy is very valuable, the extract of witch-hazel. It is sold in America as Pond's Extract. The writer has found it of great value for *external* application.

Sprains.—Rest is the main treatment. If the sprain receives immediate attention, surround the parts with cloths wrung out of iced water. This keeps down the swelling and relieves pain. Later, or if the cold applications are disliked, apply warm cloths. When all pain and inflammation have quite passed away, *but not till then,* rubbing with or without liniment will help to restore the use of the part.

Falls on the Head should receive careful attention. The child should be put to bed and keep quiet for the day. He should also receive a large dose of purgative medicine, castor-oil or syrup of senna. Cold cloths should be kept to the head and only milk diet allowed. If the child is cold warm bottles should be applied to the lower limbs, and the body gently rubbed, *but no stimulants of any kind should be given.*

Bleeding from the Nose may be controlled by the application, over the bridge of the nose, of sponges soaked in cold water. If it occurs frequently without known cause, let the child's health be inquired into. If it is a stout, evidently full-blooded child, keep the bowels free, and let the diet be very simple. If, on the other hand, the child is delicate, it should have an iron tonic, like chemical food, and cod-liver oil, and plenty of nourishing food.

Foreign bodies in the Nose and Ears, &c.—(1) If the body is in the nose, the child should be made to take a deep breath, then the free nostril closed, and a strong effort to blow through the blocked nose will often succeed in dislodging the substance. (2) If the body is in the ear, syringing may be used if *the body is not a pea or a substance that can suck up the water and swell.* Pins, bodkins, &c., should be used with the utmost care, especially in the ear, where a slight thing will injure the delicate drum of the ear and destroy the power of hearing on that side. (3) If a child has swallowed a pin, a coin, or other foreign body, purgative medicines should not be given, nor much fluid food, but plenty of soft food, like porridge, rice, corn-flour, saps, &c., which may surround the body and prevent it injuring the stomach or bowels.

Choking.—If a piece of food has stuck in the throat, support the child's head by the left arm, open the mouth with the handle of a spoon or a piece of wood, pass in the forefinger well to one side of the mouth against the cheek and push it right back into the throat. By sweeping the finger round, the mass may be hooked out.

SECTION XVI.—RATE OF GROWTH OF CHILDREN.

Period and Rate of Growth in Children:
The Value of Periodical Measurements.
Standards of Growth:
Tables showing Height, Weight, &c., at different Ages—
(1) in boys and men of the artisan class,
(2) in girls,
(3) in boys and men of the most favoured classes.
Comparison between Growth of Boys and Girls, and between Growth of Boys of different Classes.
The Relation of Height to Weight—Tables showing Increase in Weight corresponding to a certain Increase in Height.

Period and Rate of Growth in Children.

In the last section the management of children from birth up to a few years of age has been entered into in some detail. It is not necessary to follow up that section with one considering the management of children from the earlier years to the age of manhood or womanhood. The lines on which such management should proceed are practically similar in both instances. For details regarding food, clothing, exercise, &c., reference can be made to the part of the work devoted to Hygiene, from which full information can be gleaned. Investigations undertaken in recent years, however, have shown that parents and guardians of children have always at hand a simple and reliable means of informing themselves of the general state of physical health and growth of the children under their care, a means of assuring themselves that their method of watching over the bodily well-being of the children is attaining its purpose. This means consists in observing accurately, from time to time, the growth of the children in height and weight.

A large number of statistics shows that up to the age of about 22 years in boys and 18 in girls an uninterrupted increase in height occurs in a state of health, accompanied by a regular increase in weight. The rate of increase varies with the year of life, and, indeed, also with the season of the year. Moreover, a multitude of observations has shown that for each year of life there are a certain height and weight and a certain rate of increase which can be set down as the standard for that year. Diseased conditions, whether apparent or not, seriously affect this normal increase. Any wide departure from the general rule, if not actually in every case indicative of disturbance, becomes at least a signal of possible danger and a warning of the need of careful inquiry into the state of health. Here, then, is a valuable means, ready to the hands of parents and all who are in charge of children, of assuring themselves from time to time of the general health of their children and of the results of their management of them.

For the proper carrying out of the method a register requires to be kept. The name of the child is entered, and opposite each observation the date should be written. At regular periods, say at intervals of one month, the height and weight should be measured and duly noted. The height is measured from the sole of the foot to the crown of the head; shoes are, therefore, removed. The weight ought not to include clothes; and as the amount of clothing varies at different times, it is well to take the weight with clothes and shoes, and then weigh these separately, deducting their amount from the total. Besides the height and weight the measurement round the chest is valuable. It should be taken next the skin—without clothing, that is to say. The measuring tape is placed quite horizontally round the chest. The lower edge in front touches the upper part of the nipple and includes the lower part of the shoulder-blades behind. To ensure that the chest is always expanded with air to the same extent the person is made to count from one to ten, when the measurement is taken. The arms should, at the time, hang loosely by the sides.

The Value of such Periodical Measurements is shown by a variety of circumstances. Dr. Percy Boulton gives one instance that occurred at the Boys' Home, Regent's Park: "In 1875 it was found at that institution that the boys had not increased on an average 2 inches a year, so, in January, 1876, a revised dietary was used, and it was found after one year that, by this simple change, the average increase amongst the boys had been over 2 inches in stature and 6½ pounds in weight." In prisons and lunatic asylums the inmates are weighed once a month, and the information given by the scales is taken as an indication of the sufficiency of the diet in quantity and quality. But the

information is of further value. If the weight is not satisfactory, and no error in diet accounts for this state of affairs, an examination of the person is made. As a result maladies are discovered in an early stage, before other signs had made themselves manifest; and thus disease is detected at an early stage, when it may be more easily and successfully treated. It has been shown that loss of weight is one of the earliest occurrences in consumption, and may be detected before cough has begun.

Everyone knows that young people who are growing rapidly are, as a rule, more easily fatigued and can stand less bodily and mental strain than others. If regular measurements were taken and showed that a rapid increase in height was taking place, unaccompanied by a corresponding increase in weight, it would be a sufficient warning of the necessity of care and avoidance of undue exertion both bodily and mental. A boy or girl who exhibits rapid bodily growth, cannot be expected to exhibit the same mental activity as one whose energies are not so much diverted in one direction. Allowance ought, therefore, to be made in the former case for less progress in education and less inclination for school work. In such a case parents and guardians ought to refrain from endeavouring unduly to push school work, and ought rather to encourage open-air amusements and exercise. The reverse condition of unusual cleverness and devotion to books and school work, accompanied by diminished growth in height and weight, would be equally taken note of as undesirable, and instead of the mental application being applauded and encouraged it would be restrained until the verdict of the measuring rod and the scales was more favourable.

It has been very strongly urged by those who have devoted special attention to the functions of the brain and nervous diseases that such methods of regular measurement ought to be systematically employed by schoolmasters and all who have to do with the regulation of the education of children, and that physical growth rather than age ought to be the indication of the stage of progress in education. Such observations would show that mental dulness was often healthy, and would aid in distinguishing between pupils who were backward because of bodily conditions and those who were backward because of idleness and carelessness. They would also show that brilliance at school was often unhealthy and undesirable, and in need of careful restraint rather than encouragement.

Standards of Growth.

In order to obtain any benefit from the weighing and measuring of children, one must know what ought to be the height and weight of the child at particular ages, so that the ascertained height and weight may be compared with that which is taken as the standard in health. This standard has within recent years been supplied by very numerous observations made upon children and grown-up persons at various ages. Tables constructed on the basis of these observations will be given. The tables given are derived from Dr. Roberts' *Manual of Anthropometry*. At the top of each column of the table is noted the year of life, and below are given the mean height, the mean growth occurring from one year to the next, the mean weight and its mean growth from year to year. It is necessary to explain that mean height, mean weight, &c., imply the height, weight, &c., which were found to be the most common among the multitudes examined.

TABLE I.

Showing the Mean Height, Mean Weight, their Annual Rate of Growth, and the Mean Chest-girth, with its Annual Increase, of 13,931 Boys and Men between the ages of 4 and 22 Years, of the Population in Large English Towns—Artisan Class.

Age last Birthday.	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21 to 22

Table II. is derived from Dr. H. P. Bowditch, and the girls were partly of American, Irish, and mixed English, Irish, and American parentage.

It is necessary to notice the difference between the physical conditions of the boys and men of Table I. and the girls of Table II., else erroneous conclusions would be drawn. The boys of Table I. belong to the artisan class, living in large English towns. They are, therefore, not in circumstances best fitted for natural and unimpeded growth. They are statistics of boys subject to the more or less constant influence of at least not quite healthy surroundings, bad air, not too abundant nourishment, and labour begun in early youth, just at the period when growth ought to be most rapid. The girls of Table II., on the other hand, belong to a more favoured class, at least including many of the more favoured classes, likely, therefore, to show statistics of better stature and weight.

In order to show the differences in growth due to more favourable physical conditions of life, Table III. is given, dealing with boys and men of the most favoured classes, as found in English public schools, in the army, navy, universities, and medical schools. Thus Tables I. and III. will afford standards for boys and men, whether belonging to the artisan or more favoured classes, and Table II. will afford a standard for girls. Tables II. and III. will also permit a more reliable comparison to be drawn between the growth of girls and that of boys.

TABLE III.

Showing Mean Height, Mean Weight, Mean Chest-girth, and Mean Annual Growth of 7709 Boys and Men, between the ages of 10 and 23 Years, belonging to the most Favoured Classes of the English Population (Roberts).

Comparison between Growth of Boys and Girls, and between Growth of Boys of Different Classes. Comparing first of all Table I. with Table III., it is evident that the boys and men represented in the latter are in a better physical condition than those of the artisan class. At the age of 21 the most favoured class has a mean height of 2½ inches greater than

the artisan class. The tables afford no means of comparison below the age of 10 years, but at that age the most favoured class has still the advantage of 2½ inches. At the age of 16 the difference in height between the two classes is as much as 3½ inches, due to the very rapid rate of growth about that age among the favoured classes, among whom it is greatly reduced in the 18th year, while in the artisan class the greater rapidity of growth does not begin so soon, does not go on so quickly, but lasts a year longer, so that the great difference in height at the age of 18 becomes reduced during the succeeding year. These differences are undoubtedly due to the less fortunate circumstances of the artisan class, which not only diminish the rate of growth but actually lessen its total amount. Similar differences are exhibited in respect of weight and chest-girth. At 21 years of age the artisan is a mean of 16 pounds lighter than his more favoured neighbour. At 10 years of age the difference is only 1 pound, but it is gradually and steadily increased, and the most favoured class have a permanent advantage of some 14 pounds in weight. In chest-girth at 21 the artisan is nearly 4 inches less than the youth of the non-labouring class.

A perfectly accurate comparison between the growth of girls and boys is not obtainable from the tables, for the girls belonging to Table II. were not drawn exclusively from one class. But the table shows that girls attain their full height earlier than boys by between two and three years, namely at 17 years, and that their mean height is from 4 to 7 inches less than men. Even at birth there is a difference in height and weight between male and female children to the advantage of the former. The difference in weight between the two sexes and in chest-girth is also marked. What is specially worthy of note, however, is that it is between the 11th and 13th years that growth is most rapid in girls both in height and weight. After 14 growth, which began to lessen the year before, rapidly diminishes, and is reduced to very little after 16. This rapid falling off in growth is coincident with other changes of great importance discussed at length in Sect. XVII.

In the tables the figures between the years when growth becomes most rapid and then falls off are given in black type for the sake of emphasis.

The Relation of Height to Weight. It is of importance to notice that increase in weight should occur in a regular way with increase in height. The following table is given by Dr. Percy Boulton in the *Lancet* of Oct. 16, 1880, as a reliable working standard. It is deduced from the results of observations of the same children who were examined at least once annually. The children were selected as average children of healthy well-to-do parents, brought up with suitable food and surroundings, giants and dwarfs being excluded.

,,	4	,,	11	,,	,,	6	,,	3½	,,
,,	5	,,	0	,,	,,	6	,,	6	,,

The general conclusions will best be given in Dr. Boulton's own words. "I find," he says, "that average English children, brought up under favourable circumstances, grow from 2 to 3 inches a year. *A growth of less than 2 inches or over 3 should excite apprehension.* The former would indicate arrested development, and the latter a rate of growth beyond the powers of average children. Rate of growth should be regular, and, being so, prognosticates future stature, because the healthy child that grows 2 inches a year passes 5 feet at about 15, which indicates a short stature (*i.e.* if a male about 5 feet 6 inches, female about 5 feet 1 inch). The healthy child growing 2½ inches a year is 3 feet 2 inches at 3 years, and passes 5 feet at 13 to 14 years. Such child will be a medium-sized adult (*i.e.* if a male about 5 feet 8 inches, female about 5 feet 3 inches). The quick-growing healthy

child that accomplishes 3 inches a year passes 5 feet at 10 or 11, and eventually makes a tall adult (*i.e.* if a male about 5 feet 10 inches, female about 5 feet 5 inches). . . . Of course one meets with many variations, but these variations are, I believe, always abnormal. Some children seem to do their growing by fits and starts, the common diseases of children arresting, for the time, their progress, which is made up for afterwards by a supreme effort. Such growth is unnatural and often very detrimental. I believe, then, that every healthy child has its own regular rate of growth of 2, 2½, or 3 inches a year, from which it has no right to vary more than ¼ inch a year."

"Next as to weight for height, whether a child grows 2, 2½, or 3 inches a year, weight for height should be, in each case, identically the same; and all children should grow broad in proportion to their height. *Between* 3 *and* 4 *feet the increase in weight should, I find, be* 2 *pounds per inch, and between* 4 *and* 5 *feet* 2½ *pounds per inch.*" . . .

"Some children exceed these weights (those given in Table IV.) that are by no means giants, and really healthy, well-nourished children of healthy parents and favourable surroundings generally attain these averages. But what of children that fall below the standard? I find that there is a 7-pound margin of safety, and that children falling more than 7 pounds below this standard are devoid of reserve capital on which to draw, and, consequently, they succumb quickly to many constitutional diseases. This, therefore, may be called the preventive-medicine margin, beyond which lies the dangerous land of cachexia" (a depraved condition of body).

"Arrest of growth or loss of weight precedes so many diseases that it may be looked upon as a danger signal; and, if the caution is noticed before the disease point is reached, catastrophe may frequently be prevented."

These tables are given as standards for reference, and brief suggestions will be given in closing this section as to their method of use.

Each child should be weighed and its height taken once a month, or at least once a quarter. Reference should then be made to Table I. or III. in the case of boys, according to the class to which the child belongs, the labouring or more favoured class, or to Table II. in the case of girls. It will thus be seen whether the child reaches the standard for its age. The column of the table is taken headed with the age of the child at its last birthday; and in that column will be found the height, weight, and chest-girth to which it should reach. The results of each weighing and measuring should be noted in a book kept for the purpose, the date being accurately entered. The increase that has taken place since the last trial should be noted and compared with the standard in the tables. Lastly, the height of the child should be referred to Table IV., and it should be noticed whether the weight reaches to that mentioned in the table as proper to the particular height.

Of course there will be variations. Any considerable variation, however, and specially any sudden variation, should lead to careful consideration of all the child's circumstances, its food, the fresh air and exercise obtainable by it, the amount of school and other work, &c. Some change in these may at once be suggested. If no such circumstance seems to account for the departure from the rule, medical advice should be sought.

Especially between the ages of 11 and 17 should the results of the weighing-chair and measuring-rod be carefully watched. They will throw light on the question of over-pressure at school, and, if their warning is accepted, will do much to prevent it. Every school ought to have a room set apart and equipped for the weighing and measuring of the pupils. The standards of weight and height should be painted on the walls, and each pupil's height, weignt, and chest-girth should be registered at regular periods. Education would then have a better chance of being conducted on physiological principles, and with some regard to the physical development of the pupils.

SECTION XVII.—HEALTHY WOMANHOOD AND THE DISEASES OF WOMEN.

Healthy Womanhood.

The Dress of Girls:

Affections of the Generative Organs:
- *Diseases of the External Parts*—Eruptions—Sensitive Red Patches—Itching of the Genitals—Inflammation—Boils and Abscess;
- *Diseases of the Vaginal Passage*—Inflammation—Discharges (*Leucorrhœa—whites*)—Fistula—Tumours and Growths (Cancer, &c.);
- *Diseases of the Womb*—Inflammation, Ulceration, and Tumours (Polypus, Fibroid, and Cancer)—Displacements and Falling (*Prolapse*) of the Womb;
- *Diseases of the Ovaries*—Inflammation, Neuralgia, and Tumours.

Disorders of the Monthly Illness (Menstruation):
- *Absence of the Monthly Illness* (*Amenorrhœa*);
- *Irregularity or Scantiness of the Monthly Illness;*
- *Excessive Monthly Illness* (*Menorrhagia and Metrorrhagia*);
- *Painful Monthly Illness* (*Dysmenorrhœa*);

Affections of the Bladder, &c., in Women:
- *Painful, Difficult, and Frequent Passing of Water.*

Diseases of Pregnancy:
- *Derangements of Stomach and Digestion*—Excessive vomiting, &c.;
- *Disturbances of Breathing;*
- *Disturbances due to Pressure*—Dropsy, Varicose Veins and Piles;
- *Nervous Affections;*
- *Miscarriage and Flooding;*
- *Molar Pregnancy or Blighted Mole.*

Diseases after Child-birth:
- *Flooding;*
- *Milk-Fever and Affections of the Breasts*—Gathered Breast:
- *Convulsions and Insanity;*
- *Puerperal Fever.*

Sterility.

Nervous Diseases of Women:
- *Hysteria, Catalepsy and Trance.*

HEALTHY WOMANHOOD.

In the preceding section statistics have been given showing the rate of bodily growth in weight and height of both sexes. From these tables also it will be observed that in girls, between the ages of eleven and thirteen, increase in height and weight becomes more rapid than at any other period of life, while growth begins to diminish at thirteen years of age, and at the age of sixteen it begins to cease. A similar occurrence is evident in the case of boys, but several years later. This comparatively sudden falling off in physical growth is coincident with the attainment of the period of puberty. Puberty is derived from a Latin word, *puber*, signifying of ripe age, or adult. The age of puberty is the period when the development of certain organs, devoted to the function of reproduction, so advances that the person becomes capable of discharging that function. As this period arrives the energies, formerly devoted mainly to the building up of the general bodily structure, become largely diverted, and the increase in height and weight is thus rapidly diminished. It is just previous to the arrival of this period that the marked increase in stature and weight occurs. Both these occurrences are indications of critical stages in the life history of the individual. The period before puberty, the *prepuberic period*, as it is called, is a time when the nutritive processes of the body are in a condition of high activity, as is sufficiently indicated by rapid growth, and the equally rapid falling off in growth is also indicative of profound constitutional changes. Both are periods which make exceptional demands on the bodily powers, and which are, therefore, attended by risks of their own, specially so in girls in whom the changes connected with this stage of life are more rapid than in boys. It is a time of instability, a time when all the powers of body and of mind are sensitive to slight influences and easily overbalanced. It will be well, therefore, to indicate briefly what suggestions physiology has to make to parents and guardians to aid them in their appropriate guidance of girls under their charge. First of all, and in general, reference may be made to the last section where the advisability is urged of observing, at periodical times, the rate of growth in height, and the relation of height to weight, as indicative of the condition of bodily health and vigour. Any marked variation from the standard there given should lead to more detailed examination of the state of health, and if need seem, to an examination by the family physician to ensure that nothing is wrong. In this respect girls and boys are to be treated in the same way. Some special remarks are called for, however, in regard to the dress and education of girls.

THE DRESS OF GIRLS.

Conditions of Healthy Dress.—Strictly speaking there is only one purpose of dress, and that is to maintain the whole body at an appropriate and equal degree of heat. That main purpose being fulfilled, there are various secondary conditions to be kept in view. The dress ought to be light so that the bodily energy is not taxed to carry about an unnecessary weight, and it ought to be so adapted to the body as to leave unhampered all the natural movements of the body. This second condition implies not only that the movements of the limbs shall not be restrained, but also that such movements as those of breathing shall in no way be impeded, and that, as another example, no part of the clothing shall so constrict a part as to interfere with the natural flow of blood in it. The main purpose of clothing being fulfilled in accordance with these conditions, it is time enough to consider how the dress can be made graceful or becoming.

Common Errors in Girls' Dress.—It is easy to point out how the ordinary dress of women and girls breaks the above rules. It is not arranged so as to keep the whole body equally warm. There is more clothing over the hips than on any other part of the body. All the underclothing leaves the neck and shoulders practically bare, and when they are covered it is only by the bodice of the dress. Unless the sleeves are tight-fitting the arm is really exposed up to the elbows, while, owing to the looseness of the skirts, the legs from the knee downwards are insufficiently protected. If the clothing is improperly distributed as regards warmth, it is as apparently improperly distributed for purposes of easy carriage. The heaviest portion of it hangs from the waist, and the weight itself necessitates the drawing of the garments tight that they may be properly supported, so that the one evil leads to another. On the other hand, garments dependent from the shoulders are easily borne, and entail no undesirable constriction round the waist. A third point in which female dress is strikingly at variance with the conditions of healthy dress is in its undue weight. It will be admitted that the total

weight of the clothing is out of all proportion to the degree of warmth that it is required to maintain, and that if only warmth and protection are to be taken into account, much of it is superfluous. Thus the weight is not only badly arranged for easy carriage, but it is excessive in amount. This becomes a very important question in relation to exercise. The addition of one or two pounds weight needless clothing may seem a trifling affair, but when one considers the bodily energy expended in carrying these few pounds a distance of a few miles, it is easily seen that that slight extra weight may be indeed a serious burden, even in the ordinary movements of locomotion, and becomes an unconscious hindrance to free and vigorous exercise. Custom prevents this being fully appreciated, but women themselves know well how weighed down they feel when walking with clothing wet with rain. The increase in weight is not much, but it is felt as a load, just because it is more than they are accustomed to. Perhaps female dress does not err, from a healthy standard, more grievously than by the undue restriction of movement which it enforces. It is needless to say that the movements of the legs are very limited, and that running or jumping would be accomplished with difficulty. Tight sleeves seriously press on parts, especially at the armpits, and impede the circulation in the arm; garters, by their pressure below the knee, offer a very considerable obstacle to the return of blood in the veins from the parts below, and directly encourage the production of dilated veins with all their attendant evils.

The Evils of Stays, and the Deformities they produce.—These mistakes are as nothing to that of tight-lacing, and the evils they produce are small in comparison with those that attend this larger and greatest of all evils of feminine dress. The real effects of tight-lacing ought to be thoroughly considered. First of all, it undoubtedly impedes the full expansion of the lungs. In the section on Respiration it is explained (p. 254) that the act of breathing consists of an expansion of the chest in every direction; the cavity of the chest enlarges and air rushes in to fill up the lungs, and so occupy the increased space: thereafter the chest returns to its usual size, and air is thus expelled to permit of a diminution in the expansion of the lungs to fit the diminished space. The chief way in which the chest cavity enlarges is by the descent of the diaphragm, which is at once the floor of that cavity and the roof of the cavity of the abdomen or belly. When the diaphragm descends it does so at the expense of the belly cavity, on whose space it encroaches, and to make additional room the front and side walls of the abdomen bulge outwards. Now if the waist and part of the chest are encircled by a tightly drawn and, by the agency of steel, practically unyielding structure like stays, this movement of the abdominal walls cannot be developed, the descent of the diaphragm is arrested, and expansion of the chest in this direction becomes difficult. To compensate for this, enlargement must take place by exaggerated raising and widening of the upper part of the chest through movements of the ribs. The lower part of the chest is restricted in movement, and in the upper part the movement is overdone. The lungs are thus insufficiently and improperly inflated, in their upper portions having to bear an unnecessary strain, and their lower portions being seldom properly distended at all. Moreover, the constant pressure exerted by the stays forces inwards the lower ribs and specially the last two on each side, the floating ribs, which have no attachment in front, and forces in to some extent also the lower ribs next to them, so that the shape of the chest becomes actually altered, and instead of being broad and expanded low down, it is narrowed and drawn in. All this means diminished breathing space, enfeebled breathing power, and its indirect consequences it is difficult to estimate. But more than this. The pressure exerted by tight stays seriously alters the proper positions of the various organs in the abdomen. It is difficult to state with any accuracy how many different kinds of disturbance of a good state of health may arise in this way. The normal circumference of the waist ought to be from 25 to 27 inches. Under the influence of lacing this may be reduced to 20 or 22 inches, and even less, 16 inches being considered by some fashionable dressmakers the goal to be reached. Now all this constriction takes place at the expense of the space within the abdomen, and partly within the chest; for, as has been stated, the lower ribs are easily compressed from the slight nature of their attachments in front. Now in the ordinary condition every inch of space is occupied by the various organs, and the compression can only be exercised at their expense. The stomach, bowels, and liver will be directly affected, pressed together to some extent, and also to some degree forced upwards or downwards. This undue pressure tends to prevent full growth of the parts, and even if they have previously been fully developed, some degree of wasting

(atrophy) or shrinking. After death the liver on examination has been seen to bear permanent marks of the ribs pressed on it by tight-lacing. For even though the pressure is relaxed every time the corsets are removed, the continuous daily recurrence of the compression gradually establishes a permanent state of constriction, so that the parts do not return to their normal size on removal of the pressing force. It is undoubted that indigestion, disturbances of the liver and bowels—even ulceration of the stomach—have been the results of the persistent practice of wearing tight stays. Besides being themselves directly affected in this way, these organs, according to the amount of displacement they are bound to experience, alter the relations of others. Pressed upwards they encroach on the space that ought to belong to heart and lungs, breathing is disturbed, and the natural action of the heart interfered with. Palpitation, faintness, and many other heart symptoms may be the direct consequences. Then the pressure exerted downwards inconveniences the bladder, and is a very frequent cause of altered positions and disordered functions of the special female organs. Displacements of the womb, with all the manifold influences they may have on the monthly illness, are recognized as often produced by such a cause as this. While such evils as these result from the practice, what benefits, it may be asked, are supposed to be derived from it? It can hardly now be maintained that the "taper-waist" is desirable from its beauty. Any standard of beauty as regards human form is derived rather from that which appears to be most perfect in its development and most natural in its outlines. Greek statuary shows with perfect distinctness the views held by the ancients on the subject. The Venus of Melos shows the natural outline of the waist, and is a model of what its sculptor must have esteemed an ideal of beauty. The wood-cut in the text, taken from a photograph, while it sufficiently indicates the outline, cannot suggest the dignity and grace which the statue itself so wonderfully exhibits. Let anyone compare this outline with that given to the female form in any fashion-plate, and there ought not to be much difficulty in admitting that the "taper-waist" is, strictly speaking, a deformity artificially produced. It is urged, however, that stays are necessary to distribute the weight of the clothes and to give some support to the back. As to distributing the weight of the clothes, it has been already indicated that the suspension of so many clothes from the waist, which is supposed to necessitate the use of the corset, is itself a grave mistake, and there can be no doubt that the clothes can be so adjusted from the shoulders as to render any such artifice as stays unnecessary. As to the need of supporting the back, that is rather the effect than the cause of stays. For the fashion in which, even from infancy, children

Fig. 182.—The Venus of Melos, showing the natural female form.

are hedged in, from the hips to the arm-pits, by a more or less stiff wall, is undoubtedly productive of feeble development and deficient vigour of the great muscles which run right down the back on each side of the back-bone. It is one of the first laws of growth that moderate and regular exercise of a part of the body strengthens that part; in short, that its strength is in proportion to the use that is made of it, and that, on the other hand, disuse of a part inevitably

tends to weakness and wasting. Now the swathing to which infants and young children are subjected so restrains the activities of the muscles of the trunk that proper exercise of them is impossible, and the corsets of later years even more effectually impede their activities.

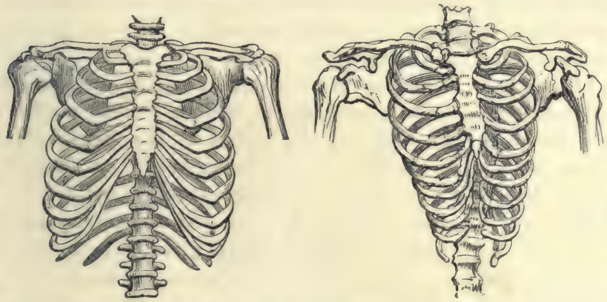

Fig. 183.—The Bony walls of the Chest.—That to the left shows the natural position, that to the right the deformed position due to tight lacing.

It is therefore the stays that render the back weak, not the weakness of the back that renders the stays necessary.

Suggestions as to Healthy Clothing.— These are some general criticisms meant to point out the errors, from a point of view of health, in the general character of woman's dress. It is only women themselves, however, who can successfully carry out any reform in this direction. Fashion is too imperious to bow to the authority even of health, and, probably, the necessary reforms will not all be carried out till the time arrives when health becomes fashionable. But even though the outward appearance of woman's clothing must be regulated, not by a question of comfort and physical well-being, but mainly by the whim and caprice of the rulers of fashion, every woman has it in her power, while submitting to the fashion-makers, to adapt her clothing in order that it may fulfil more thoroughly than it usually does its obvious purposes. That is to say, if a woman must conform to what other people wear in the matter of a cloak or a jacket, a bodice and skirt, and if she must cut her bodice in accordance with the mood of the times, and adorn her skirt with furbelows or frills as the newest style directs, she can at least exercise her own will as to the nature of that portion of her clothing which is not meant to be visible. Underclothing consistent with health is not a very elaborate affair. There ought to be a garment next the skin made of wool or flannel, shaped to fit easily. A knitted "suit" would probably be the most useful. It should reach up to the neck, fitting it as close as is comfortable, and ought to be provided with sleeves down past the elbow, also easy fitting. The lower part of this combination garment would extend below the knee. Over this linen garments might be put on according to the pleasure of the wearer, but they ought not to be made with that exuberance of material, both in length and breadth, which is customary, and which necessitates so many creases and folds and doublings. Thus a chemise might be made with some respect to the length and circumference of the body it was designed to clothe. Any petticoat ought not to be simply fastened round the waist, but ought to be suspended by something like braces from the shoulders, or by buttoning on to a light bodice. But if any additional *heavy* underclothing is required for more warmth it ought to approach as nearly as possible to a divided garment that will cover each leg separately. Such *light* petticoats as are worn for appearance need, of course, no such division. Now it cannot be said that underclothing of such description as this demands anything in the nature of stays, for there is no great weight in it, and what weight there is is borne from the shoulders. Stays, therefore, ought to be entirely discarded as an article of dress, of whatever description they may be, for children, girls, and young women. It may be admitted, however, that nursing mothers require more support to the breasts than ordinary clothing supplies, and that for them some form of corset is required. But this ought rather to be in the shape of a bodice made of stouter material than usual, and such a bodice could be readily made without the steel bands and other stiff structures of which ordinary corsets chiefly consist. Women who have naturally more largely developed breasts than usual could adopt such a form of support as would easily meet the requirements of comfort and appearance. This healthy form of underclothing that has been suggested, if it were adopted, need not interfere with the wearing of a dress and its bodice made according to the requirements of the times, and thus health and fashion would each have a due amount of regard paid to them.

As regards covering for the feet and legs, woollen stockings ought to be worn, but the usual method of securing them by garters round the knee is highly injurious. Any garter to be

sufficiently tight for this purpose must press on the veins of the surface, and thus impede the circulation in the skin. This obstacle to the free upward flow of blood from the foot and leg causes an accumulation of blood in the veins; the pressure of blood becomes so increased that the walls of the veins are apt to yield, especially in older persons, and varicose veins or a swollen and inflamed condition of the skin are in time the results. They often lead also to a feeling of weariness and pain, just owing to the interference with the circulation. The stockings ought, therefore, to be secured by suspenders connected with the shoulder brace or bodice. The form boots and shoes ought to take is considered under HYGIENE.

It cannot be too strongly impressed upon mothers and those who have the charge of girls that attention ought to be paid to the clothing of girls, to ensure that the purposes of clothing are carried out, and are not carried out in any way that is inconsistent with the highest degree of health and healthy growth. Many of the most serious evils of a woman's life, and an innumerable number of the minor ailments, that seem little in themselves but nevertheless among them make the difference between an active, bright, and energetic woman, and an ailing and feeble woman, are the result of mistaken notions in clothing of which the woman was the victim during the period of childhood and youth. Grown-up women may dress themselves as they please, and may violate the laws of health, if they choose to sacrifice themselves to foolish notions of what is desirable in female form, but they are not entitled to humour their fancies in the dress of their children, if the methods they adopt are likely to hinder the healthy growth of the children, or tend even indirectly to encourage feebleness.

THE EDUCATION OF GIRLS.

Higher and University Training.—It used to be a common subject of discussion whether women are intellectually inferior to men, and it was also commonly concluded that they are. Whether that be so or not, it is a fact that woman was for many centuries kept in subjection, and that indeed it was not till the advent of Christianity that woman was called to occupy her position as not the inferior but the complement of man. If there is any truth in heredity, this long-continued subjection must be taken into account, and the suggestion of the old question that girls should not receive so complete an education as boys, because they are unfit for it, must be set aside.

Without attempting a logical definition, we may say that education has as its objects the leading out or developing of all the powers of mind and body; and even if it were admitted that woman is mentally inferior to man, that is only an additional reason for more careful, and complete, and well-adapted training. Linked with man in life's work, and one with him in destiny, why should woman be less carefully prepared for the duties of life or less fitted for its issues? Accordingly, now as complete an education is being gradually extended to girls as is given to boys, and in America, where especially the education of girls has been pushed with much eagerness, a university education is not debarred to them.

Opinions of various Authorities in England, America, and France.—Although sufficient time has hardly elapsed since this movement began its full swing to enable one to estimate accurately its effects, nevertheless a very considerable body of testimony is put forward to show that girls are not only fitted intellectually for the highest developments of education, but are not necessarily injured physically. Thus Mrs. Henry Sidgwick, speaking of her experience at Newnham and Girton Colleges at Cambridge, says, "the experience of Girton and Newnham certainly shows that the danger need not be alarming. The actual number of women who even temporarily break down at Cambridge from the effects of work is exceedingly small in proportion to the whole; and as for the average health of the hard-working students it is little to say that it would compare very favourably with that of girls who are laboriously devoting themselves to the pursuit of amusement. I think it may be asserted that it would compare favourably with the average health of young women generally in the class from which our students are drawn. In fact, overwork is an evil to which attention ought to be continually given, not so much because the danger of it is great, as because it is to a large extent preventible. A delicate woman may go, and frequently has gone, through the course of training for an honour examination without any injury to her health, and even with positive gain to it, from steady and not excessive work, with power, to a great extent, to choose her own days and hours for it; but even a strong one is liable to make herself ill unless she will observe the ordinary common-sense rules of health as to sleep, food, exercise, recreation, and other things."

Miss Freeman, President of Wellesley College, Massachusetts, judging from the experience of three colleges for women in the Eastern States of America, the Vassar, Wellesley, and Smith Colleges, where in 1883 there were more than 1000 women students, says the results have been "so manifestly good that they would go on, greatly trusting that in educating women's heads they would not hurt their hearts or ruin their constitutions."

Mrs. Richards of Vassar College offers proof of the possibility of giving girls a complete university education free from danger to health, in the shape of statistics concerning a large number of women who had studied and graduated at first-class institutions, and who had passed out of them from five to fifteen years before the date of inquiry. As a result of the inquiry "physicians had acknowledged that they were surprised at the comparatively good health of the educated women of America as shown by these statistics." According to Mrs. Richards, "experience had shown that if a girl was well cared for from twelve to eighteen, then went to college from eighteen to twenty-two, during that period there would be no trouble whatever." She hoped that those who had the control of education in this country (England) would look closely into that matter. It was, of course, very difficult to keep acquainted with those who had left college, but if some kind of record could be kept of their subsequent health, that would be the best answer which could be given as to the danger of the physical effect of education upon girls.

In France there is a magnificent college at Sèvres for women, the École Normale Secondaire Supérieure, concerning which Professor Darmesteter says "the system for the higher education of women had already produced good results, and he trusted that it was opening up a new era in the education of women." Similar testimony comes from Germany.

There is, of course, another side to the question. The modern objections to an education for girls as complete as that for boys centre round the opinion that such education unfits girls, by the nervous strain to which they are subjected, for their duties in life as wives and mothers. There is evidence in support of that opinion. Professor Loomis, of Yale College, regarding the increasing physical deterioration of American girls, says "the cry to our older colleges and time-honoured universities is: Open your doors that the fairer part of creation may enter and join in the mental toil and tournament! God save our American people from such a misfortune!" This, however, it is right to say, was the opinion of Professor Loomis at a much earlier period than the testimony in favour of university education for girls already given. Dr. Withers Moore of Brighton gave his address as President of the British Medical Association in 1886, on the subject of the higher education of women. He asks, "Is it for the good of the human race, considered as progressive, that women should be trained and admitted to compete with men in the ways and walks of life, from which heretofore (as unsuited to their sex) they have been excluded by feeling and usage, and largely, indeed, by actual legislation?" He answers that "it is not for the good of the human race, considered as progressive, that women should be freed from the restraints which law and custom have imposed upon them, and should receive an education intended to prepare them for the exercise of brain power in competition with men. And I think thus," he continues, "because I am persuaded that neither the preliminary training for such competition work, nor the subsequent practice of it in the actual strife and struggle for existence, can fail to have upon women the effect of more or less (and rather more than less) indisposing them towards, and incapacitating them for, their own proper function—for performing the part, I mean—which (as the issue of the original differentiation of the sexes) Nature has assigned to them in the maintenance and progressive improvement of the species. . . . This 'higher education' will hinder those who would have been the best mothers from being mothers at all, or, if it does not hinder them, more or less it will spoil them." Dr. Moore cites in support of his opinion the views of Herbert Spencer, Dr. Matthew Duncan, Sir Benjamin Brodie, the late Dr. Edward H. Clarke (U.S.A.), Dr. Emmet of America, Mr. Lawson Tait of Birmingham, and others, mostly specialists in diseases of women.

The general strain of these opinions will be sufficiently indicated by the following from the late Dr. Thorburn, of Owens College, Manchester: "The struggle for existence on the part of single women, and the capacity of a few of their number to ignore, with safety, the physiological difficulties of the majority, are demanding opportunities for education, and its honourable as well as valuable distinctions, which cannot and ought not to be refused. Unfortunately, however, up to this time no means have been found which will reconcile this with the physiological necessity

for intermittent work by the one sex. It becomes, therefore, the duty of every honest physician to make no secret of the mischief which must inevitably accrue, not only to many of our young women, but to our whole population, if the distinction of sex be disregarded."

If, however, we carefully consider the burden of the objections raised to the full education of girls, and the recent developments of female education in England and America, some way out of the maze created by these differences of authority seems possible. We have to consider that many women find the necessity of earning their livelihood in occupations requiring careful education and a large amount of mental toil, and we find a large and daily increasing number of women who value the highest education, not for what it will bring, but for its own sake. The claims of neither of these can be disregarded. Up to the age of twelve years there is no reason why girls should not receive an education equal to, if not identical with, that given to boys. It is after that age that difficulties arise due to the special circumstances of sex. It is about that age that special developments take place in the training of boys dependent upon their intended course through life. If they mean to go in for commercial pursuits, the education is moulded in accordance with that intention, if for professional life, they go on to training preliminary to the universities. If they are boys who, by reason of their position, can afford to pursue an education whose immediate object is culture, and whose ulterior object may be determined at a much later period, according merely to fancy or inclination, the higher education of the secondary school and the university is proceeded with. This age is also the time when, in the case of girls, the special circumstances dependent on her sex require to be taken into consideration. The Americans seem to find that if, after that age, whatever may have been the system adopted before it, the education of girls is directed with special regard to her physiological necessities, that is with regard to the monthly changes which periodically occur, all danger may be averted. This almost implies that girls be taught, after that age, in secondary schools set apart for themselves, where they do not enter into competition with boys, and where, on that account, a periodical relaxation of studies may be permitted to occur without throwing one set of pupils out of line with another in rate of study. Still further to diminish all tendency to overstraining, the best American opinion seems to indicate the advisability of abolishing competitive work and examination among girls, and it is found that the love of work itself supplies sufficient stimulus to requisite exertion, that, even where competition is not engaged in, the eager desire for learning requires careful watching to hold it sufficiently in check. Similarly colleges for women only, where like care and supervision are exercised, seem preferable to mixed colleges where an unhealthy straining to excel is almost certain to exist. Such a regulation of study, in accordance with girls' physiological requirements, is only possible in an institution exclusively devoted to girls.

Overpressure in education has as pernicious an effect on boys as it has on girls. That evil is got rid of by proper regulation of study, and, along with care in diet, &c., by means of a due amount of exercise and recreation. This general rule is applicable to girls as well as to boys. The special objection in the case of girls is that the *continuous* mental application is not consistent with the special demands made upon a girl's energies at regularly returning periods connected with her peculiar functions. That objection, we believe, is met by such provisions as have been already indicated, which, however, as we have already said, can only be properly made in secondary schools and in colleges devoted exclusively to the female sex, and regulated with due regard to these functional peculiarities. In short, the objections that have been urged against the according of the highest education to girls do not strictly lie against the education itself, but against the system on which it has been conducted. The arguments are not logically against giving the same education to girls as to boys, but against giving that education *in the same way*. We believe the difference in the testimony that came from America at an early period in the movement for higher education, which was not in its favour, and the later testimony, when better methods had been devised, and which was in its favour, is simply due to that fact that the necessity for periodical relaxation had not been recognized at the early period, and was fully realized at the later. Thus one teacher in giving evidence before the State Board of Massachusetts, in 1874, said: "*At certain periods* I think that study with girls should wholly cease for some days. I refer to girls from twelve to twenty years of age. Anyone who has taught boys and girls—in separate schools, I mean—must have noticed the greater proportionate irregularity of attendance of the latter, and as a parent he would know the reason

and the necessity of cessation from work." Another says, "Could the custom of keeping girls between the ages of thirteen and nineteen out of school and at moderate rest *during certain periods* become established among us, a certain number might suffer restraint not absolutely demanded, but the general result would be an incalculable gain to the health, present and prospective, of the inhabitants of this commonwealth." Dr. da Costa, of New York, maintains that "common sense and the teachings of physiology point in the direction of lessening, as far as practicable, work *at a time when the whole system is depressed*." Dr. Cohran of the New York State Normal School has been "compelled to the conclusion that the sexes cannot be educated *on the same system* with advantage, and that the physical disadvantages under which the female labours render it necessary that a system be devised so elastic, with so much optional work, that the female may rest, at least comparatively, *as the occasion requires*." Those parts of the opinions have been printed in italics, which show clearly that the objections taken are not to the higher education in itself, but to the difficulty of reconciling it with the periodical change in women, and that difficulty later methods have to a large extent overcome.

The conclusion of the whole matter seems to be, let girls have the same education as boys and along with boys, if need be, up to the age of twelve years, overpressure being carefully avoided in the case of one as in the case of the other, a due amount of recreation and exercise being daily insisted on; after that age deny not to girls secondary and university education, but let it be conducted in institutions restricted to them, but as fully equipped and conducted by as able teachers and professors as similar institutions for boys, where, however, periodical variations in the amount and degree of mental effort can be arranged for in accordance with the periodical variations in the amount of energy that can be devoted to nervous activity, with proper regard to other requirements. By such means the world will be blessed with wise and cultured women, and will not be without vigorous wives and mothers, not less capable of the highest duties of womanhood, because to the sweet instincts of nature they add the rich treasures of a cultured mind.

THE FEMALE GENERATIVE ORGANS.

At the age of from thirteen to sixteen years, in temperate climates, changes occur in girls which indicate that a stage has been reached in the development of special organs, and that the girl has become capable of her peculiar functions. The main change is the occurrence of a discharge from the genital organs, which, because of its recurring at regular intervals of twenty-eight days or one lunar month, has been called the "monthly illness." Before considering what the discharge means, it will be necessary briefly to describe the organs concerned.

The female generative organs situated within the body are the womb or uterus and certain appendages, the ovaries, and tubes which lead from them to the womb. The relation of these parts is shown in Fig. 184.

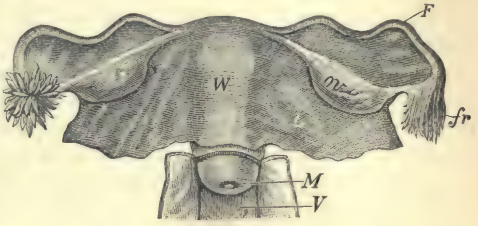

Fig. 184.—The Womb and its Appendages.

W, the womb. *ov*, the left ovary. *F*, the left fallopian tube, and *fr*, its extremity. *L*, the ligament of the womb. *M*, the mouth of the womb. *V*, the genital passage, opened up.

The womb or **uterus** is situated deep in the cavity of the pelvis (p. 22) between the bladder which lies in front of it, and the end of the large bowel which lies behind it. It is pear-shaped, and is on an average three inches long, two broad, and one thick. It is composed mainly of muscular fibre of the involuntary kind (p. 70). In its centre is a narrow cavity (the walls being very thick) running up towards the broad end of the pear-shaped organ, and opening at the narrow end at what is called the mouth of the womb. The inner surface next the cavity is lined with mucous membrane (p. 307), in which there are glands. The organ is richly supplied with blood-vessels and nerves. By means of a transverse slit, the lips of which are, however, in the virgin state closely applied to one another, the mouth opens into the passage of the vagina, which communicates with the outside, and is about 5 inches long. The womb is kept in position by ligamentous structures, which are lax enough to admit of a moderate degree of movement. Now the womb is flattened on its front and back walls, and if a pear be imagined as pressed somewhat flat in this direction it will be easily understood that the appearance of a corner at each side of the

broad end will be produced. The womb has such a corner at each side of its upper end, and from each of these corners a tube passes off, the **fallopian tubes.**

Fallopian Tubes. Each tube has the appearance of a thick cord, 3 or 4 inches long. It consists mainly of muscular tissue like that of the womb, and in the centre of its whole length runs a canal, the inner wall of the tube being lined by a membrane also like that of the womb, but having no glands imbedded in it. At the end next the womb the canal will admit only an ordinary bristle, but at its other end it is wider. The end distant from the womb opens into the cavity of the belly, is trumpet-shaped, and provided with fine finger-like projections or fringes. (See Fig. 184, *fr.*) The tube of each side is further connected with the womb by a broad band of tissue, a ligament. Connected with this ligament is the **ovary,** one on each side of the body.

The Ovaries are flattened oval bodies, each about 1½ inch long, ¾ inch wide, and nearly ½ inch thick. They are attached to the womb by means of the broad ligament referred to, and to one part of the ovary the fringe of the fallopian tube of its own side is connected. It is in the ovaries that the ova are produced,

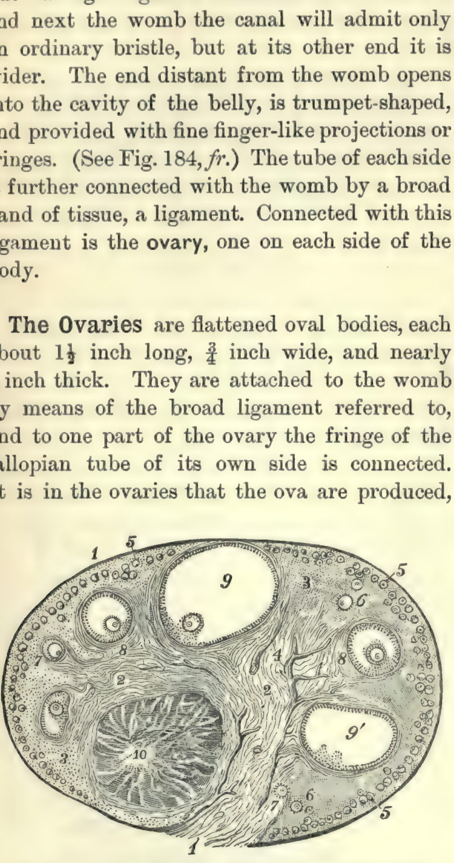

Fig. 185.—Section of Ovary magnified, showing ova in various stages of growth.

1, Capsule of ovary. 2, Fibrous substance of ovary. 4, Blood-vessels. 9′, Sac from which ovum has been removed. 10, Space from which ovum has been discharged filled up with blood-clot, &c. For meaning of other numbers, see text.

the female element in the production of new beings. The ovaries are supplied with many nerves and blood-vessels. Each ovary contains a multitude of ova or eggs in different stages of growth. In the ovaries of a female child at birth they are already visible, and it has been estimated that no less than 70,000 may be present in the two. Each ovum or egg is about the $\frac{1}{100}$th of an inch in size. Fig. 185 shows a section or slice of an ovary, the little round bodies being the ova, those near the surfaces (5) being undeveloped, those deeper (6, 7, &c.) being more mature. In process of growth the ova pass more deeply into the substance of the ovary. Instead of lying in groups, one becomes separated from others by growth of substance between them. As one becomes more mature it becomes surrounded by an envelope or capsule, which by and by forms a sort of bag round it. The ovum becomes attached to one part of the wall of the sac and fluid is produced separating the rest of the wall from it, and the fluid increases till the egg is, as it were, connected to the inner wall of a minute bladder. (See Fig. 185, 8 and 9.) As it grows, the sac with its ovum approaches near the surface of the ovary till it bulges from the surface. The continued increase of fluid finally causes the little bag to burst, and the ovum is discharged. The ovary at this time is very freely supplied with blood. The discharged ovum would readily drop into the cavity of the belly but for the fact that at this time the fringed end of the fallopian tube is applied to the ovary, and the ovum is received into the canal of the tube, and passes down the canal till it reaches the womb.

Thus during the early years of a girl's life the ovary is developing, and the ova it contains are maturing. It is not till the twelfth year or upwards that the first ovum becomes ripe and is discharged, and when that period is reached the girl has arrived at the age of puberty, that is, the age when she is capable of conceiving. At the time when an ovum is about to be discharged, changes take place in the womb; an extra supply of blood reaches it, and the changes occur which lead to the appearance of the discharge. From the time when the first ovum becomes mature and is discharged, as a general rule, one becomes ripe after another at intervals of twenty-eight days. Thus from thirteen years or so onwards regularly every month an ovum becomes mature and is discharged, and its period of ripening and discharge is attended by the changes in the womb alluded to, and so there is the periodical occurrence of the monthly illness. For a certain number of years—up to the age of forty-five or thereby—these changes regularly take place till the organs become exhausted, the period of the "change of life" arrives, these occurrences cease, and the capacity of conception has passed away.

MENSTRUATION.

Menstruation (*The Menses—Monthlies—The Periods—The Courses*) is the term applied to the process, whose external evidence is the discharge from the genital organs. The word is derived from the Latin *menstrualis*, meaning monthly, from *mensis*, a month.

Time of Appearance and Symptoms.—It is some time between the ages of twelve and sixteen years that the appearance of the monthly discharge indicates that the internal generative organs have arrived at some degree of maturity. Even before that occurrence various other signs indicate a change coming over the girl. An alteration takes place in the figure and gait owing to expansion of the hips and fuller and more rapid development of the breasts. The whole figure becomes more plump and rounded, and the girl less awkward and angular, and more graceful. Her manners also change. She becomes more sedate and less wayward, more timid and bashful, but also more gentle and loving. The actual period of the first illness varies with the climate and other circumstances. In Britain the age of sixteen is that at which it most commonly begins; in France it is earlier. The general rule is that it appears earlier in warm countries and later in cold countries, the mean being in a temperate climate. The date of appearance is also affected by the conditions of life. It is earlier among those who live in towns, and later among country girls. Luxurious habits of living, the use of warm stimulating foods, &c., hasten it; while among those whose lives are more simple and primitive, or who live among conditions of hardship, it is delayed. It is also influenced by the constitution, and its appearance may be long delayed in a delicate girl. There are also exceptional cases on record, cases where the illness has appeared remarkably early, or where it has not appeared for many years past the usual time. The first monthly illness is frequently accompanied or preceded by some degree of feverishness, pains in the back, a sense of fulness in the abdomen, and feelings of great weariness. It is also a time when a girl may manifest a variety of nervous symptoms, and may be liable to hysterical attacks. The first portion of the discharge is clear, later it is tinged with blood, and gradually it becomes almost pure blood, the blood then gradually diminishing till finally the discharge becomes free from blood and then ceases. The symptoms which preceded and accompanied the discharge pass off, and in a few days the girl is in perfect health.

The regular illness is not established all at once. The girl may suffer from some of the preliminary symptoms, which lead the mother to conclude her illness is going to begin, and after a few days they may pass off without any or but a very slight discharge appearing. And this may occur at one or two periods without any flow of blood. Or one illness may occur in the regular way, and one or two periods may then pass with only a threat of its occurrence. Parents must not be alarmed at such irregular occurrences. Nor are they to take, as is too often done, any steps to force the discharge, such as administering drastic purges and other kinds of medicine. The general health of the girl remaining good, no alarm need be entertained, and in any case no haphazard methods should be resorted to. (Refer to p. 483.) One thing it is desirable to notice here. The external passage (vagina) is almost closed in the virgin by a membrane called the **hymen**, which stretches across it near its entrance. Through a narrow opening in its centre, or through several smaller openings, the discharge from the womb escapes externally. In rare cases no opening exists, and the discharge does not escape but is pent up within. The girl may, at the usual time for the appearance of the discharge, have the symptoms that have been noted, but there is no flow; and thus one period after another may pass, the discharge accumulating behind the barrier. The accumulated discharge will in time form a swelling, even though it gives rise to no other symptoms, and there will be the appearance of a tumour in the abdomen enlarging with each returning period. This, taken with the absence of any discharge externally, has more than once given occasion for most unjust suspicion. In such a case as this the point to note is that on no occasion has the discharge ever appeared. If any discharge had at any period appeared, it would have proved that the way was open.

Once the discharge has been fully established it should return at the regular periods during the whole of the child-bearing epoch. It is, however, interrupted by pregnancy, and does not, as a general rule, occur during suckling. Its disappearance under any other circumstances is to be regarded as a disturbance of health, which will probably be attended by other symptoms also. The **duration of each illness** varies in different persons. According to one authority the most

common length of time is eight days, then three, and then four. The quantity of discharge during one period it is also impossible to state with definiteness. From 2 to 6 ounces may be stated as extremes which are within the limit of health. Any larger quantity should lead one to seek competent advice. While four weeks is the usual time that elapses from the beginning of one illness to the beginning of the next, there are variations quite consistent with health. One woman may "alter" every three weeks, and another only every six weeks. All departures from what is stated to be the general rule are to be judged by the custom of each person and by the condition of her general health.

The discharge comes mainly from the inner surface of the womb, and while it lasts the womb is in the condition of having a greatly increased blood supply, and of being in consequence fuller and heavier than during the interval between two periods. These changes in the womb, as already noted, are coincident with similar conditions in the ovary, attending the ripening and discharge of an ovum. In the virgin condition the ovum passing down the fallopian tube into the womb undergoes no change except that of breaking down and becoming dissolved.

The Change of Life.—At the age of forty-five or thereby, earlier or later in different individuals, the regular periodical illnesses begin to cease. They rarely cease at once, but become irregular. The "illness" returns at irregular intervals, and gradually the discharge diminishes in amount. It also greatly varies, being at one time scanty and at another very profuse, till it finally ceases. The womb at this time becomes smaller in size, and the ovaries shrivel rapidly. At this time the woman is in an unstable condition of health, and liable to many minor ailments, and also to some more serious. She is liable to headache, flushings of the face, and disturbances of the digestive and nervous systems. When this period is safely past, however, a time of good health may be looked forward to with some confidence.

Vicarious Menstruation.—This is the term which has been applied to a discharge of blood coming periodically from some part of the body other than the womb, and taking the place of that discharge, which is absent or very scanty. Instances of such menstruation are not very common. But there have been cases in which bleeding from the lungs, stomach, nose, &c., occurred at the usual period, and seemed to be the means of relieving the system when the ordinary discharge was wanting or scanty.

The Management of the Monthly Illness.—Details of the nature of the monthly illness have been given above, in so far as they seemed advisable for the purpose of communicating some intelligent appreciation of the character of occurrences of which every woman's body is the seat. It is but in accordance with reason and common-sense that a woman should have some degree of accurate knowledge of so important a function. Disturbances of this function are surprisingly common, are, indeed, apparently becoming more and more common, many of the conditions of modern life directly disposing to them. That they are the cause of much suffering, borne largely in silence, because of the natural modesty of women and dislike to seek advice on so delicate a subject, is known to every medical practitioner of even limited experience. Ignorance is undoubtedly mischievous, and a certain amount of knowledge on the part of every woman desirable. Nowadays the only question is how, when, and by whom ought the necessary information to be imparted to every girl. Every medical man recognizes that a little knowledge of the subject would enable women to avoid much of the misery and suffering they incur by their ignorance. For this purpose the above details have been given as plainly and simply as seemed to suit the circumstances of the case, and for the same purpose the following general directions as to the management of the "illness" are given.

It is because the occurrence of the monthly illness is natural and periodic that women, so familiar do they become with the process, pay little heed to its indications, and do not much take it into consideration in regulating their habits of life. In arranging for their work or their pleasure too little account is taken of it, though every woman knows pretty accurately the time of its return. Even when some disturbance arises connected with it, less attention is paid than would be to disorder of the same extent of any other function. All this is the very reverse of what ought to be. For, at the very outset, it must be remembered that at the period of the illness the whole system is in a highly-strung condition, extremely sensitive to every variety of influence; the nervous system, in particular, is peculiarly impressionable, and the person, therefore, more open than at any other time to disorder of various kinds. It would only, on this account, be in accordance with

reason and common-sense that special care should be taken while the illness lasts, and for a brief period both before it and after it, to maintain good bodily health, and to guard against everything likely to affect it. Thus common-sense would suggest that exposure to cold, to damp, to draughts, and such like should be avoided. Thus during the period mere jumping out of a warm bed and placing the bare feet on a cold floor or wax-cloth has often been the cause of serious illness. Wet clothing and wet feet are specially hurtful. If women would not permit the familiarity of the process to make them forgetful, it would not be necessary to insist on these obvious precautions. It requires very little thought, moreover, to make one perceive that, at a time when so much bodily energy is directed to one function, and when so great a drain on the system is present, less, considerably less, than the usual amount of exertion ought to be undertaken. Indeed, during the days that the illness lasts, much more rest than is customary ought to be indulged in, no work requiring any strain should be undertaken, fatigue should be carefully avoided, the ordinary duties should be lightened, and some rest and quiet taken during the day. This is not always possible; but every endeavour ought to be made, even when the usual day's duties must be performed, to make them as light as possible, and to undertake no exertion that can be avoided. If this is so with even necessary duties, it is excessive foolishness for a woman to expose herself to undue excitement during the period, specially the excitement of a round of pleasure or gaiety. Social gatherings, dances, games implying physical exertion, such as lawn-tennis, boating, riding or walking excursions—all these should be refrained from at such a time. Those who are in charge of houses ought not to leave the illness out of account in arranging their domestic concerns. The dreaded "spring cleaning" and the inevitable "washing day" ought to give way when necessary, and mistresses ought not to forget that some days of apparently slovenly and half-hearted work may have a reason other than than that of idleness or carelessness, and ought when needful to lighten the burden of work to their servants accordingly. Those who have the care of young girls, whether their own daughters or not, do not fulfil their duty to them unless they exercise supervision over them sufficient to prevent them by their ignorance incurring needless risks.

Warm clothing is particularly needed during the period. Of the kind of clothing enough has already been said, but the desirability of some flannel clothing may again be urged.

As regards food not much special direction ought to be required. In the sections on Food full explanations are entered into regarding the quantity and quality of foods necessary for the maintenance of vigorous bodily health, and the relation of these to work is discussed. But it is plain that when special demands are made on the system, as they are at each recurring menstrual period, special care needs to be taken that a due quantity of nourishment is supplied. At such a time any deficiency in quantity of food or any error in kind will become most evident and most hurtful. Often at this period women are less inclined for food when it is most needed, and are too prone to quiet any appetite that is present with cups of tea, which, while they refresh and stimulate for the moment, supply no real nutriment. Plain, simple, easily-digested food of the ordinary kind at regular intervals is very necessary. At the same time too plentiful or too rich feeding is also injurious. Rich dishes, pastries, &c., are not to be encouraged. It is also too common to attempt to relieve the feeling of depression or exhaustion by stimulants. They cannot supply the place of appropriate nourishment, and are apt to lead to bad habits. It is always those who do not take fit nourishment that are most prone to turn to stimulants, and it is always they who are most injuriously affected by alcohol, since it quickens the waste going on in the body without affording any material to supply it. As a general rule the use of stimulants is to be condemned. The circumstances that make them useful are considered in discussing scanty and excessive menstruation in the latter part of this section.

The question of exercise for girls is as important as for boys, and is discussed elsewhere. It is only necessary to say here that, during an illness, as much rest should be taken as possible, and for a day or two after the period also. Active exercise during that time is the greatest possible mistake.

Bathing is to be avoided during the illness, and in particular cold bathing.

PREGNANCY AND ITS MANAGEMENT.

Conception.—Every four weeks, as has been stated, in the adult woman an ovum becomes ripe and is discharged from the ovary. It is caught by the extremity of the fallopian tube and passed down the tube towards the womb. If the changes arising from conception do not

occur, the ovum breaks down and disappears. If, however, shortly before it leaves the ovary, or during its descent of the fallopian tube, the ovum is met by the male element, which enters into it and fertilizes it, a set of changes occurs in it which lead to the formation of a new being. The material supplied by the male consists of a thick whitish fluid, in which the microscope reveals curious bodies, represented in Fig. 186, formed of an oval part, called the head, which is about the $\frac{1}{8000}$ of an inch long, and of a tail, the $\frac{1}{400}$ of an inch in length. They are called **spermatozoa**, and they are the essential element supplied by the male for conception. The fluid having been introduced into the female in the act of sexual intercourse, the spermatozoa find their way upwards into the womb and on to the fallopian tube, partly by the lashing movements of the tail, and if in their course they meet an ovum, still in fit condition, one or more spermatozoa entering it produce conception. Among the earliest changes that thereafter occur in the ovum is one by which, from the original single cell, a mass of cells is produced. Fig. 187 shows at 4 ova, magnified. Soon after the entrance of the spermatozoa the

Fig. 186.—Spermatozoa, the male element in conception.

Fig. 187.—First changes in the Ovum after conception.
1, 2, and 3 are enormously magnified; 4, less so.

ovum divides into two (1 of fig.); each of these two then subdivides into two, making four (2 of fig.); each of the four subdivides, so that eight are formed, and the process goes on to sixteen, thirty-two, sixty-four, &c., until a mulberry-shaped mass of cells (3) is formed, all derived from the original single cell or ovum. This process is supposed to occupy about eight days, and to occur while yet the ovum is descending the fallopian tube, and about the end of that time it reaches the womb, which has meanwhile been prepared for its reception, and where it is detained till the new being is more fully formed. It is from the mass of cells thus produced that the body of the child is gradually developed.

While conception is more likely to result from connection shortly before or within a few days after an "illness," there is really no period at which intercourse may be had and conception not be possible.

The Growth of the Offspring.—When the ovum which has been fertilized by the action of the male element reaches the womb it is not much larger than its original size, about the $\frac{1}{120}$ of an inch. It becomes attached to the walls of the womb in a peculiar way. Before its arrival changes take place in the inner lining membrane of the womb, causing that lining to become much increased in thickness, and owing to the increased thickness the surface is thrown into ridges and furrows. The small ovum apparently is detained in the womb by falling into one of these depressions, and becoming buried, as it were, by the ridges of the thickened wall growing round and over it. About the third or fourth week after conception the ovum has become completely imbedded in the wall, in which it forms a little swelling. Meanwhile by this time the surface of the ovum is not smooth and regular as it originally was, but is

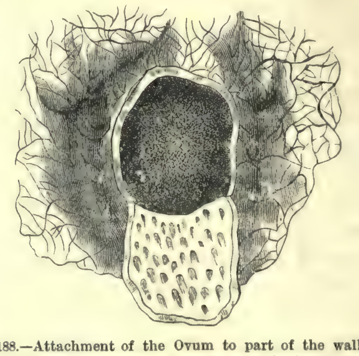

Fig. 188.—Attachment of the Ovum to part of the wall of the Womb. Part of the membranes covering over the front of the ovum has been turned down.

covered by a set of shaggy projections, termed **villi**. These villi are the result of changes going on rapidly within the ovum. They become imbedded in the substance of the wall of the

womb, which completely surrounds the ovum, and thus an intimate connection is effected between the body of the mother and the growing offspring. At this period the condition of things is represented in Fig. 188, where the ovum with the shaggy projections of its own lining membrane is shown resting on the wall of the womb, which has grown up around it so as completely to surround and cover it. The ovum is thus shut up in a little chamber in the wall of the womb, and is shut off from the cavity of that organ.

In the early period of its formation the new being is called an **embryo**, and in the later period before birth it is called a **fœtus**.

It is evident from Fig. 188 that as the embryo grows the swelling in the wall of the womb will grow larger and larger, and will gradually encroach on the space belonging to the cavity of the womb, until at length, with increased growth, the part of the wall which covers over the embryo will bulge right across to the opposite side, will, in fact, come into contact all round with the rest of the wall of the womb, and will become merged into it. This happens after the second month of pregnancy. The shaggy projections, that have been mentioned as growing out from the wall of the ovum, undergo increased growth at that part of the ovum opposite to the part of the womb on which it rests, and at that place blood-vessels come to occupy their interior. At other parts of the ovum they shrink and disappear.

Formation of Membranes and After-birth.—That part of the wall of the womb on which the ovum rests undergoes special development, and as the result of the special growth on the part of both the womb and ovum at that place, a special structure is formed, called the **placenta**, by which the structures of the embryo and those of the mother come into intimate relationship, and in which the blood belonging to each comes into such close contact that exchanges of material can take place between them. It is by means of the placenta that the nourishment of the growing offspring is obtained, it being a bond of union between offspring and mother, the agent through which nourishment is conveyed from the blood of the mother to the child. The placenta is also called the **after-birth**, from the fact that after the birth of the child it is separated and expelled from the womb. By the end of pregnancy it forms a disc-like mass, measuring 7½ inches across, ¾ inch thick, and about 20 ounces in weight. Connected with it near the middle is the **umbilical cord**, by means of which the growing embryo is attached to the placenta. Running within the cord are two arteries which carry the blood *from* the embryo to the placenta. In the placenta the blood is distributed in large spaces, and comes into close communication with the blood of the mother, by means of which its purity and nourishing qualities are maintained. From the placenta the blood passes back along the cord in a vein to the embryo, to which it gives up the requisite supply of material for continued life and growth.

To return to the ovum. We have seen that after conception it divides into two cells, then into four, and so on, till a mass of cells is produced, which dispose themselves in such a way that a hollow sphere is formed. It is from the outer layer of this sphere that the shaggy projections are thrown out which become connected with the part of the wall of the womb that has covered over the ovum, forming an outer membrane. On a part of the sphere the embryo begins to develop, and as it grows the parts of the sphere beyond the place where it is developing rise up round it, and finally meet and close over it. Thus the embryo comes to be inclosed within a membranous sac of its own, called the **amnion**, while it maintains its connection with the parts beyond by a cord, the umbilical cord. As the embryo grows, fluid is formed within the sac, and thus the embryo as early as the second month is floating in fluid contained within a sac, and connected with the wall of the mother's womb by means of a cord and the placenta. With further accumulation of fluid the amnion enlarges till it comes into contact with the outer membrane already mentioned, with which it becomes fused. So in the later stages of pregnancy the fœtus is freely movable in a mass of liquid contained within a large sac formed of the blended membranes, and is suspended in the liquid by the cord, the other end of which is attached to the placenta, which is in close connection with the wall of the womb, the womb itself being completely filled by the sac and its contents. In the course of labour the membranes are ruptured and the liquid escapes, in common talk "the waters break."

Progress of Growth at different months.—In the course of the third month of pregnancy the ovum, with its growing embryo inclosed within its membranes and floating in the fluid, comes to occupy the whole cavity of the womb. As the embryo continues growing the womb must needs enlarge with it.

After the end of the third month of preg-

nancy the growing offspring is now called a fœtus, and is so called till birth takes place. At this time the fœtus measures from 5 to 6 inches in length, and weighs about 4 ounces. Already at this time the sex is distinct, the outline of the body is complete, the eyes and ears are formed, and the nails have commenced to form.

At the end of the fourth month the fœtus has increased to 7 inches in length and nearly 9 ounces in weight. A slight down, instead of hair, begins to appear on the scalp and surface of the body, and brisk movements occur, though they may not yet be felt by the mother.

With the end of the fifth month the length has increased to from 8 to 10 inches and the weight from 10 to 12 ounces. Early in the fifth month the first movement is usually detected by the mother, and this is called the period of quickening, though, as has already been said, this is only the time when the mother feels the movement, which has previously occurred unperceived by her.

At six months the growing child is 11 to 12½ inches long and weighs more than a pound. The nails are solid, and eyebrows and eyelashes have begun to form.

In the course of the seventh month the length increases to from 12½ to 14 inches, and the weight is considerably increased by deposit of fat under the skin. In the male child the testicles begin to descend from the cavity of the belly towards their proper position.

By the end of the eighth month the length of the child is usually about 17 inches, and the weight 4 to 5½ pounds. The skin is red and covered with down. In the male child one testicle has completely descended, usually that of the left side.

At birth the average length is from 19 to 24 inches, and the average weight 7 pounds.

Male children are usually larger than female children. While 7 pounds is an average weight there are many variations. 5½ to 6 pounds weight means a very small child, and 12 to 13 a very large child, but such extremes are now and again met with.

The Duration of Human Pregnancy.— The average duration of pregnancy is between 274 and 280 days, or about forty weeks. It is roughly counted as nine calendar months. This period should be estimated from the time of conception to the time of birth. But the time of conception, that is, the time when the male element meets the ovum and enters into it, it is impossible to learn, for the period of conception is not necessarily the same as the period of sexual intercourse. The ovum may be fertilized even before it has left the ovary, or in any part of its course down the fallopian tube before reaching the womb. Conception may not take place thus for several days after intercourse, or it may take place shortly after intercourse, according to the distance the spermatic fluid has to travel before reaching the ovum. The time is, therefore, dated from the end of the last monthly illness, and the usual course is to count 280 days from the last day of the last illness. Conception is believed usually to occur about a week after the end of the last illness; the duration of pregnancy is counted as nine calendar months, so that the time of confinement as likely to occur nine months and one week from the last day of the last illness, that is about 280 days. This supplies a ready method of counting. From the last day of the last illness reckon nine months forwards, and add seven days. Thus, a woman ceased to be ill on the 7th January; nine months forwards gives the 7th October, and adding seven days, we have the 14th October, as the probable date of delivery. A shorter method is to count three months back instead of nine months forwards, and then add the seven days. Thus three months back from 7th January is, of course, 7th October, and seven days gives 14th October as before. As another example, suppose the 10th February to be the last day of the last illness, three months backwards gives the 10th November, and adding seven days we get November 17th as the probable date of confinement.

This method of counting is based on the fact that, as a general rule, the monthly illness ceases during pregnancy. But the ovum that becomes fertilized may not be the one whose ripening was at the time of the last monthly illness, but it may be the ovum of the succeeding month whose maturing was not attended by the monthly discharge, because conception had occurred. That is to say, conception may have occurred either within a few days after the last illness, or immediately before the succeeding illness was due. This gives a difference of three weeks. If, then, one has accurately known the last day of the last monthly illness, and has properly counted 280 days (or nine months and seven days) from that time, and if the confinement does not occur within a week after the estimated date, it may be expected not to take place for an additional fortnight, that is altogether three weeks after the originally fixed date.

While 280 days have been mentioned as the ordinary duration of human pregnancy, there is good reason for believing that very considerable variation in the length of time may occur, and yet the pregnancy be a perfectly natural one. Cases are on record where the only possible conclusion was that pregnancy had extended to 295 days. In Scotch law and according to the French Code the utmost limit is 300 days.

Signs of Pregnancy.—It may at the very outset be observed that up to the fourth month it is not possible to obtain any certain sign of pregnancy. Indeed, it may be said that the eighteenth week is about the earliest time when any really reliable evidence can be procured. It is possible for experienced persons to be deceived even long past that period, and women who have already borne children are occasionally themselves under the delusion that they are with child up to a time very close on that at which confinement would be expected. At the same time there are signs present very early in the course of pregnancy that, in ordinary cases, are accepted as sufficiently conclusive, which, however, ought not to be taken as satisfactory evidence against a woman protesting against such a conclusion. These early signs are:

stoppage of the monthly illness,
morning sickness, and
changes in the breasts.

Stoppage of the monthly illness (*cessation of menstruation*) is usually the first sign of pregnancy, for as a general rule throughout pregnancy there is no discharge whatever. There is, however, a number of cases in which the monthly illness does not cease immediately after conception, but goes on for a month or two thereafter, creating some doubt in the woman's mind as to the period of conception. In a smaller number of cases the illness occurs, almost as usual, up to even the fifth or sixth month, and in much fewer cases seems to occur regularly throughout the pregnancy. Some doubt may be occasioned in such cases, as has been already said. It is, however, much more important to remember that the monthly illness may cease for many reasons totally unconnected with pregnancy. It is quite common for the illness to become very irregular, to recur at long intervals, or to cease altogether for many months in young persons, as an effect of a depressed general system, or of some disturbance of health totally unconnected with the generative organs. Various disorders of the generative organs also cause interruption of the periodic illness for long periods. While, therefore, cessation of the illness in a married woman will quite properly lead one to suspect the occurrence of pregnancy and to seek for further evidence, it would be grossly improper on account of this alone to suspect anything of the kind in the unmarried. Unfortunately this has too often been done most unjustly and with most unhappy results. Such a sign as this must not be interpreted by itself. For instance it has happened that while, as regards the womb itself the illness has occurred, the discharge has not found an outlet owing to some obstruction of the passages. The discharge has been pent up within the cavity of the womb; and this has gone on month after month, the material accumulating within the womb and producing enlargement, and when it has gone on long enough the appearance of swelling of the abdomen. Such swelling, taken with no appearance of monthly illness, has seemed conclusive evidence of pregnancy, with grievous results to innocent persons. By itself then this suppression of monthly illness is not to be held as offering any sufficient evidence one way or another.

Morning sickness is another common occurrence early in pregnancy, but like the former it is not constant, nor yet is it reliable. It is specially in the morning and early part of the day that the sickness is felt, hence the phrase "morning sickness," and it wears off as the day advances. The feeling of sickness is generally accompanied by vomiting. It is commonest in the first months of pregnancy, beginning about the fourth or fifth week, and often disappears after the womb begins to rise up into the cavity of the belly, that is in the course of the fourth month; but it occasionally lasts through the whole nine months, producing much distress and great exhaustion. After the few early months it may disappear to return during the last months, owing probably to local irritation of the stomach caused by the proximity of the much-enlarged womb. Many mothers hardly suffer from it at all. Others are not afflicted with sickness, but with other kinds of digestive trouble, heartburn specially, water-brash, flatulence, acid indigestion, and so on. Different persons are affected in this respect in different ways, and even as regards the same person the course of one pregnancy may be very different from that of another. One curious form of digestive disturbance is the aversion that may arise for certain foods formerly enjoyed, and

the craving for others of an unwholesome, and in some cases, even loathsome character.

Changes in the breasts begin in the early weeks, and are at first feelings of fulness and tenderness, and sometimes even of sharp pain. The breasts feel firmer to the touch also, and the veins of the skin over them are more marked. About the ninth week the nipple is more erect and prominent from the greater supply of blood. Around the nipple is a dark circle, called the areola. After the ninth week the colour of this areola deepens, and the areola itself becomes larger; the little elevated points present in the ordinary condition of the breast become more prominent and marked. These appearances are always much more pronounced in dark than in fair women. In dark women also about the fifth month an outer circle of faint colour may be perceived, called the secondary areola, which has been described as presenting the appearance produced on a dingy white, or tinted surface, by drops of water falling on it, and taking out the colour. The deepening of colour is due to the deposit of an additional quantity of pigment in the deep layer of the skin, and since the deposit is more or less permanent the change is most marked in first pregnancies. Increased darkness of colour also occurs in a line about a quarter of an inch broad along the middle line of the belly from the navel downwards. In some women also patches of a yellowish-brown colour appear on the forehead, cheeks, breast and neck, which, however, disappear shortly after the birth of the child.

These signs, then, of suppression of the monthly discharge, morning sickness, and similar digestive disturbances, and changes occurring in the breasts are the earliest indications of the pregnant state. Not one of them, however, taken alone is to be regarded as offering satisfactory proof of that condition, but all taken together, while not affording conclusive proof, are to be regarded as very strong presumption of such an occurrence.

Among the later signs of pregnancy are—

enlargement of the abdomen,
movements of the child—quickening, and
detection of the sounds of the child's heart.

Enlargement of the abdomen does not occur till towards the fourth month, when the womb begins to rise upwards from the cavity of the pelvis (p. 22) into the abdomen. In the earlier weeks the increased weight of the womb, due to its added contents, causes it to sink more deeply in the pelvis, and this produces in the second month rather a flattening of the surface of the belly. By the fourth month the womb requiring increased room has risen upwards, and may be detected above the edge of the bony ridge in front. By that time the person will be conscious of an increasing tightness of the dress, and by the end of that month the hollow round the navel is less marked than usual. A progressive increase in size occurs till at the seventh month the hollow has disappeared, and the navel is on a level with the rest of the skin, after which time it begins to extend beyond the general surface. But, as with the other signs, this one must not be considered alone, for a tumour in the belly, dropsy connected with the ovaries, discharges pent up within the womb, as already noted (p. 487), and other causes will produce enlargement, which only skilled persons can distinguish from one another. Nor yet can this sign be taken along with that of suppression of the monthly illness as conclusive evidence of pregnancy, because monthly discharges prevented from escaping will occasion both conditions.

Movements of the Child—Quickening.—A mother first becomes conscious of the movements of the child in the womb at a period, roughly stated, about the middle of pregnancy. More accurately it is from the sixteenth or seventeenth week of pregnancy onwards that the movements may be detected, and if the date be noted it affords valuable aid in determining the probable time of delivery. The period at which these movements are felt is called the **period of quickening**, because it was thought that then for the first time the child became active. In reality it is active before this, but about this time the enlarging womb comes into contact with the belly walls, and so the movement becomes sensible to the mother. The sensations are actually due to movements of the child, kicks, movements of the knees, &c., and are at first felt as feeble flutterings, which, as pregnancy advances, become more and more pronounced, till they may even occasion pain and cause the mother to cry out. By the fifth month they may be excited by pressing with the hands from the outside on the belly walls. In later stages the movement is easily visible, and one may be able to feel with the hand the outline of a knee, &c., as it passes along the wall of the womb. Now this is one of the most convincing signs of pregnancy; but it is yet possible to be in error regarding it. Rapid movements of gas in the intestine, irregular contractions of the muscles of the belly wall, heaving movements due to a bulging of the wall of a large artery (aneurism),

&c., may be mistaken for movements of a child, and have been so mistaken by women who had previously borne children. Moreover cases of what have been called "phantom tumour" have occurred, in which enlargement of the belly and the sensation of jerking movements were due to spasmodic contractions of the muscles of the walls of the belly.

The detection of the sounds of the child's heart is a sign which affords unmistakable evidence of pregnancy. The beating of the child's heart may be detected about the eighteenth week of pregnancy. It is found by placing the ear on the belly at a part midway between the navel and the bony part at the bottom of the belly and a little either to the left or right. Instead of applying the ear directly the stethoscope is commonly used. The beat is distinguished from the pulse of the mother by its rapidity. It generally ranges from 130 to 160 per minute, and is more rapid in female than in male children. The position mentioned is the one in which the sound is heard, because at this stage of pregnancy the child is usually placed head downwards, with its back forwards and to the left or right, usually to the left. Some portion of its back is thus brought into contact with the front wall of the womb, and as the womb is in contact with the belly wall the sound is conducted. The child may, however, be lying in some unusual position, so that the sound is not conducted to the place mentioned, and it may be difficult to find any part of the belly wall at which it is heard. While, therefore, the detection of the sound is conclusive evidence of the presence of a child and of its life, the non-detection must not be taken as conclusive evidence of there being no pregnancy or of the death of the child. It will, therefore, be understood that this is a sign requiring to be sought for by a skilled person.

There are other signs a physician would endeavour to find to confirm his view of the presence or absence of pregnancy, but it is needless to detail them here.

On the whole, then, it will be evident that it is not always an easy matter to settle definitely whether a person be pregnant or not. The absence of the monthly illness, the occurrence of morning sickness, of changes in the breasts, and of enlargement of the belly may lead one to entertain a strong positive opinion, and yet that opinion may be mistaken. If, however, a competent person detects with certainty the beating of the child's heart, continued doubt is not possible. This cannot, however, be detected much before the fifth month. The necessity for caution in coming to any conclusion, particularly in certain circumstances, cannot, therefore, be too strongly insisted on.

The Management of Pregnancy.—The months of pregnancy are periods of considerable anxiety and trouble to most women, and are especially so to those who pass through them for the first time. It is natural that women, pregnant for the first time, should seek advice and counsel from more experienced female friends, who are as a rule too willing to offer the results of their experience, and to impress their lessons on the mind of their less experienced friend. As a rule, however, the advice is as various as it is plentiful, and often very conflicting. It is, moreover, so often accompanied and enforced by narrations of misfortune and trouble that the mind of the receiver is often perplexed and confused, but also filled with grave fears, which she can hardly utter. Now it must not be forgotten that pregnancy is a natural process, that nature is usually sufficiently able to accomplish well her purposes, and that the vast majority of pregnancies if allowed to pursue, without meddlesome interference, their natural course end naturally, easily, and successfully. The woman, who is looking forward with some quite natural anxiety to the birth of her child, should turn a deaf ear to the tales of woe, which friends too often delight to communicate, and should endeavour to preserve a cheerful and equable frame of mind, which is the only condition justified by the facts. She ought early in the months of her pregnancy to determine who shall be her medical attendant, and if she has any doubts or misgivings, or really wishes advice on any particular point, she ought without hesitation to go to him for it. If she has made even an ordinarily good choice, she will find her doubts removed, and her mind quieted, and will have an authority, to whom the advice of her friends can be submitted, and by whom it can be, without offence to them, satisfactorily disposed of.

Much may be done by pursuing a regular method of living to make the months pass in comparative ease and comfort. To aid in accomplishing this some general directions will be given.

Food.—There is no special diet suited more than another to the pregnant state. The rule is plain nourishing food at appropriate and regular intervals. Very rich and highly-seasoned dishes are undesirable. In some cases there is

a craving for certain articles, and provided they belong to the nourishing class of foods, the yielding to the craving in moderation is not to be denied; but in a few cases the craving is for unwholesome and nauseous substances. This is to be considered as morbid, and ought to be held in restraint not only by the person herself, but also by all who surround her. Stimulants are neither necessary nor desirable in ordinary circumstances. It is not denied that they are often useful and perhaps also necessary, but the usefulness and necessity ought to be judged of by the medical attendant and not by the patient herself or her friends.

In the later months a bandage, broad in front and narrow behind, if properly fitted so as to support the womb without compressing it, will give much comfort. It should be put on while the person lies in bed on her back, and should be removed at night.

Clothing should be carefully adapted to the varying condition of the person, and should never be at any part tight fitting. Enough has already been said on the subject of corsets (p. 473), but in the pregnant condition their evils are much increased. "The Romans were so well aware of the mischief caused by compression of the waist during *gestation*, that they enacted a positive law against it; and Lycurgus, with the same view, is said to have ordained a law compelling pregnant women to wear very wide and loose clothing."

Exercise.—During the early months of pregnancy there is difficulty in taking walking exercise, because the womb sinks down lower than usual on account of its increased weight, and makes walking attended with discomfort if not actual pain. When the womb has risen upwards, owing to its requiring more space, this difficulty becomes less, and thus during the middle months of the nine, exercise is more pleasant and less fatiguing. Towards the end of pregnancy it becomes increasingly difficult because of the size and weight, and also because the joints become more lax in preparation for the period of delivery. Gentle, regular, and moderate exercise, obtained by walking, should, however, be persisted in throughout the whole period, never, however, so as to cause pain. The patient must not allow her inclination to be completely at rest so to overcome her as to prevent her obtaining the slight change and beneficial stimulus, which a short period in the open air will secure to her. In particular the desire to avoid the public gaze ought not to keep the person completely indoors for the last month or two of pregnancy as it too often practically does. Gentle carriage exercise need not be forbidden, but jolting over rough roads is plainly likely to be injurious. Lengthened shopping expeditions and such like are too frequently the cause of miscarriage during the early months as well as during the later months. While more rest is needed than in the non-pregnant state, an increased amount of rest ought not to be permitted to lead on to idle, lazy, and indolent habits.

Bathing.—Baths should be taken in moderation, extremes of heat and cold being carefully avoided.

The Breasts require some attention. Pain, swelling, and tenderness of the breasts are among the early signs of pregnancy, as we have seen, and require no special attention. But if the breasts are small and ill-developed, and the nipples pressed in as they may be by the pressure of stays, trouble after delivery may be saved by drawing them out with the aid of a breast-pump, or the ordinary breast-exhauster (Plate VIII.). Should the nipples be tender the best means of toughening them is by the use of the tannin and glycerine of the chemists. The use of alum and whisky is too apt to make them hard with a tendency to crack.

Medicine.—It is a matter of the greatest moment, for the comfort of the patient, that daily movement of the bowels be obtained. This ought if possible to be secured by diet—the use of oatmeal, fruits like figs, prunes, stewed apples, &c. Sometimes medicine is needed, and many take a dose of castor-oil at regular intervals. It is comparatively safe, though nauseous, but it often occasions "false pains" near the termination of the pregnancy. The writer is in the habit of recommending not castor-oil but Hunyadi Janos mineral water. If there is any doubt at all of obtaining daily an easy and sufficient movement of the bowels, he advises the mineral water to be taken each morning before breakfast, in the quantity the patient finds suits her, and it ought to secure a gentle motion without purging after the lapse of an hour or two. The average quantity is a claret glassful, but the patient should begin with a small wine-glassful and go up, if necessary, till the suitable quantity is found. It should be then regularly taken. It is a simple remedy, practically incapable of doing harm, and its use he has found, over and over again, to conduce greatly to the health and comfort of the patient. No other medicines should be employed without proper advice.

LABOUR AND ITS MANAGEMENT.

The Stages of Natural Labour.—Natural labour is the process by which the child is expelled from the womb and born into the world. It occurs at the end of the ninth calendar month of pregnancy, or, as has been already mentioned, about 280 days after conception. It probably begins at the time when a monthly illness would have been due, counting such illness as recurring every twenty-eight days, that is to say, at the time when the tenth monthly illness from the time of conception would have become due. As we have seen, the womb is composed largely of muscle. As pregnancy advances it becomes greatly enlarged to make room for the growing child. Its walls also become greatly increased in thickness, and the muscular fibres become increased not only in number but also in size. The chief force in labour is the contraction of these muscular fibres. The fibres are so arranged in the walls that when they contract and shorten they tend to diminish the size of the womb and of its cavity, and thus act in the direction of squeezing out of the womb its contents. The walls are so strong that when they contract in this way they exert a very great force, and are thus able to overcome very great resistance to the expulsion of whatever the womb contains. The amount of resistance will depend on the bulk of the contents—on the size of the child—and on the width of the passage through which the child has to pass before reaching the outside. The first resistance, however, occurs at the mouth of the womb, which is closed or at least not much wider than to admit the passage of anything thicker than an adult's finger. The child can, therefore, make little advance along the passage till the mouth of the womb has been sufficiently dilated or stretched, and this opening up or dilatation of the mouth of the womb is, accordingly, the first thing to be accomplished in the labour process. It forms **the first stage of labour**.

It has been already mentioned (p. 485) that the child is inclosed in a bag of membranes, floating in a liquid (the waters), having a cord attached at the navel by which it is connected with a mass called the placenta or afterbirth (p. 485) attached to the inner wall of the womb, by means of which union with the mother is maintained. By the contraction of the muscular walls the bag of membranes, with its contents of waters and child, is pressed on and forced in the direction of least resistance, that is, against the mouth of the womb. The mouth being slightly open the membranes and their contained fluid bulge into the slight opening and are a very active agent in widening it. Sometimes the mouth of the womb is rather rigid and the force pressing the membranes into it is so great that the pressure of the fluid bursts them, and a gush of water takes place—"the waters are broken," as the phrase is. The part of the child's body that is directed downwards—usually the head—is then pressed directly against the mouth of the womb, but it being larger and not able to insinuate itself into the small opening as the bulging membranes did, dilates it much more slowly, and the labour is all the more tedious. During the first stage of labour, then, it is desirable that the membranes should remain unruptured and that the "waters" should not escape.

It is the contractions of the muscular walls of the womb that occasion the pain characteristic of labour. They are not continuous, but last only a brief period, so that there are periods of pain followed by periods of freedom from it. The intervals of rest prevent exhaustion of the muscular walls and also of the mother, and at the same time permit the mouth of the womb to be gradually and gently opened up without risk of injury, while the child also is allowed an interval to recover from the compression which, in the later stage of labour, each contraction exerts on it. The pains during this first stage are of a cutting or grinding character, and are usually trying to the mother, because she feels as if no progress were being made by them. She is often, on this account, irritable and restless under them, frequently changing her position and uttering complaints. A considerable interval elapses between each pain in this stage, perhaps twenty or thirty minutes at first, but the interval gradually lessens as the opening up of the womb becomes more nearly sufficient, till towards the end of this stage they may be returning every five minutes or oftener. The pain is usually felt more in front. While this stage lasts efforts of straining or pressing downwards do not render any assistance in opening up the mouth of the womb, and they ought not to be encouraged, since they throw away the patient's strength, which ought rather to be reserved for the second stage, when they are of great value. It is of advantage, however, for the patient to move about her room, and interest herself in some gentle occupation during the intervals of rest, rather than confine herself to bed.

The second stage of labour begins when the mouth of the womb is sufficiently widened to permit each contraction of the womb—each pain—to urge the child through the opening and down the passage to the outside, and it ends with the birth of the child. During this stage the bag of fluid is no longer a help, but rather a hinderance, and, therefore, it is proper for the attendant to introduce a finger into the passage, and when a pain occurs to press the point against the bulging and stretched part so as to burst through it. This permits the escape of the water and allows the advancing part of the child to come directly into contact with the walls of the passage, which it is best able to stretch. The upper and inner end of the passage is formed of the bony rim of the pelvis and is practically unyielding, so that the child in advancing through it must have its body compressed and moulded to permit of its passage. Were the pains constant the continued compression might be injurious to the child, and so the intervals of rest, though brief, are beneficial. The remainder of the canal is formed of soft and yielding structures, which the advancing part of the child stretches with more or less ease. But here again the periods of contraction, followed by intervals of rest, permit the parts to be stretched to some extent and then to be released from pressure. Thus the widening of the passage is accomplished gradually and without risk of injury.

During the second stage the patient naturally fixes her body, bends the knees up towards the body and the head towards the chest, grasps something fixed with the hands, and holding her breath presses down. The pressure thus exerted by the walls of the belly greatly aids the process of delivery. During this period, therefore, the patient remains in bed, and the more quietly she lies, the more firmly she holds her breath, while the pain lasts, and the more vigorously she presses down, the more speedy will be the termination of her suffering. In a few cases, when the child is advancing with great rapidity, and the parts are being stretched too quickly and forcibly for safety, one does not permit the patient to have anything to grasp, and, instead of urging her to hold her breath and press down, one asks her to cry out, to refrain as much as possible from pressing down, and thereby to prevent the pressure by the walls of the belly. The pains during the second stage are felt at the back, and the patient is much aided by some one pressing the back firmly with the palm of one or both hands. Towards the termination the mother feels something pressing low down, and the bulging and opening out of the external parts indicate the near approach of delivery. The advancing part of the child appears at the external opening, which it widens as the pain occurs. With the interval of rest it retreats. When another pain occurs it advances further, stretches the opening still more, and with another interval again retreats. The child may seem just about to be born, when the pain ceases for a minute or two, and it goes back again. This sometimes disheartens a mother somewhat, but it is desirable, for it permits the gradual widening of the opening, and diminishes the risk of tearing. Finally, with a great effort the first part of the child is born, the rest of its body quickly follows, and the delivery of the child is accomplished.

The third stage of labour, however, remains. It consists in the expulsion of the after-birth, with which the cord passing from the child's navel is connected, and it is usually unaccompanied by much pain, and occurs within from five to thirty minutes of the birth of the child. It is often expelled from the womb when the child is born, and lies in the passage for a little time, till it is removed by gentle pulling on the cord by the attendant, or ejected by contractions of the walls of the passage itself.

The after-birth is separated from the wall of the womb by its contractions. But with its separation blood-vessels of the mother are opened and a raw surface is left. From this for an instant blood escapes, in considerable quantity, but is speedily checked by the contraction of the womb, which now becomes permanent, squeezing the mouths of the bleeding vessels together and thus closing them. Some blood remains in the cavity of the womb, which is reduced by the contraction to very small dimensions. It gradually oozes away as discharge. Any clots that remain do not escape so readily, and excite small contractions to get rid of them. These are the occasion of the **after-pains**. So that the more thoroughly the womb is emptied of all clots after the separation of the after-birth, the fewer will be the after-pains; and they will be severe and troublesome for a day or two if any quantity of clots has remained behind. Usually after-pains are absent in a first labour.

The Duration of Labour varies naturally with the size of the child and the width and capacity of the canal through which it must

pass, as well as with the age, vigour, and build of the patient. It is longer in first labours than in those subsequent, on an average twice the length. The average for first labours is roughly twelve hours, and for others six. The first stage occupies generally two-thirds of the whole time. At the same time it is not possible to gauge what is likely to be the time occupied during the later stages from that occupied by the first. For a labour which has begun quickly and gone on quickly for some time may become much slower as its termination approaches, or the reverse may occur.

The Position of the Child in Labour.—In the womb even in the early months of pregnancy the child usually bends forwards, and in the later months the head is bent forwards upon the chest, and the thighs bent upwards to the belly, the knees and elbows also, and the arms crossed and folded over the breast. This is called the **attitude of the child**, and it suits best the cavity in which it is placed.

It is usually the head that is directed downwards towards the mouth of the womb. At full time this is the rule in 96 per cent of cases. But other parts of the child may present themselves first at the mouth of the womb, and the word **presentation** is used in referring to the part of the child that thus offers itself first at the opening of the womb. Thus there are head presentations as already mentioned occurring in 96 out of every 100 cases. The other extremity of the oval which the child forms in the womb may, however, be first, and thus there are said to be breech presentations, in which the buttocks present first. This occurs once in every 45 births. The child may be across the mouth of the womb—a cross or transverse presentation—and so a shoulder or hand, &c., descends first. These are happily rare, for they are very unfavourable.

Usually the head descends first, with the face directed backwards and to the right side, and when it has advanced a considerable way it turns slightly so as to make the face look directly backwards, and directed thus the child is born, the back of the head passing outwards and upwards in front of the mother, the face sweeping round the back wall of the passage. When the head has been born the face turns upwards towards the mother's right thigh, and this movement allows the shoulders to descend in the direction of the canal in which there is greatest room. As soon as they have been born, one in advance of the other, the birth of the rest is easy. In its descent along the canal the child's head is moulded more or less in proportion to the difficulty of the labour, so that when born it has a peculiar elongated appearance, which gradually passes off in the course of a few days.

The Management of Labour.—Labour is a natural process, and in the vast majority of cases is best accomplished by nature's own unaided efforts, without any necessity of meddlesome interference. It is only now and again that interference is necessary or desirable. As, however, in nearly every case where interference is necessary, there is a particular period when it may be more easily and successfully employed than at another, a woman in labour ought to have from the beginning the services of a skilled attendant. If on examination he finds everything going on properly and naturally, it is a great comfort and encouragement to the patient to be told so, and if, on the other hand, he finds something that requires active interference, he can choose the best time for it, and is ready for the emergency. It cannot, however, be too strongly stated that the cases where interference is really necessary are not so common as is supposed, are indeed rare in proportion to the natural and unaided births.

The woman should be in a quiet airy room, with a fire burning in the grate, and with all proper conveniences at hand. Her companions should be few, and cheerful. Of all the plagues of a lying-in room that woman is the worst, who beguiles the hours of waiting by relating her experiences, and recalling all the horrors and misfortunes of which she has heard as attending the termination of pregnancy.

The bed should be prepared in the usual way. On the top of the under sheet is then placed a square of waterproof, in the place over which the patient's hips will be as she lies in bed; above the waterproof is a blanket folded into a square of sufficient size. Or the blanket may be folded so as to be of greater length than breadth, and is so placed that as one part gets soiled it may be drawn forwards from below the patient and a fresh portion thus brought under her. It is well also to have a square of waterproof *below* the under sheet. On a screen before the fire is hung, ready folded, another blanket to replace the soiled one when it is withdrawn, and also a sheet similarly folded. In the first stage of labour it is well to allow the woman to be up, and moving about or occupying herself between the intervals of pain. When the second

stage comes on, she should get into bed, lying on the left side with the knees drawn up and fixed by means of the feet pressing against a stool or such contrivance, while the upper part of the body is fixed by the patient tightly grasping a towel fastened to something at the head of the bed. The strong downward pressure the woman can thus exert is of great value in the second stage, though it is only a waste of strength in the first. The patient should have on the clean clothing she means to wear during her confinement to bed, but it should all be well gathered up above the waist out of the way of discharges, and lightly fastened round the waist should be a petticoat which will protect the clothing to some extent, and be easily slipped off over the feet, when the labour is over.

At the commencement of labour, if the bowels have not been properly moved for some time before, it is well to clear them out by means of an enema injection.

During the labour drink, cold water, &c., is not to be refused, but, of course, ought to be partaken of only in moderate quantities. A warm cup of tea may be refreshing, but stimulants are to be given only by medical orders, and without such advice no drugs should be taken with the idea of terminating the confinement more quickly.

Just when the child is being born the patient should refrain as much as possible from severe pressing down, that the risk of tearing the parts may be diminished. It appears also that the common custom of placing the hand over the external parts to hold against the advancing head is more likely to lead to rupture than to prevent it.

In anticipation of the birth of the child, its clothing should be hanging before the fire, a bath, warm water, a clean sponge, and some good soap should be in readiness, also a pair of scissors, and two pieces of linen thread, each piece about a yard long, and twice doubled with a good knot at each end, for the purpose of tying the cord. Some olive-oil should also be at hand. As soon as the head is born the attendant should pass the fingers up to feel whether the cord is round the neck. If it be, the finger should be able easily to slip it over the shoulder. One hand is then placed over the outside of the belly, and grasping the womb, as it were, gentle pressure is to be made following it downwards as it descends. The body of the child will usually be born within a few seconds of the head without any further aid, though gentle pulling may be made with one hand on each side of the head, if aid seems needed from threatened suffocation of the child or other cause. Rarely the membranes are not ruptured during labour, and the child is born still inclosed in them. They must in such a case be quickly torn, else the child will be suffocated. The child is said in such circumstances to be born with a "caul." This, of old, was considered a sign of good omen, and seamen used to seek to obtain the caul under the belief that it protected the wearer from death by drowning.

The Treatment of the Newly-born Child.—As soon as the child is born it should be placed in a position in which it may breathe easily, bedclothes being kept off its face, &c., and mucus wiped from the mouth and nostrils with a clean napkin. Usually the mere contact of its naked body with the air causes a gasping movement followed by regular breathing and lusty crying. If this does not at once occur, it is ordinarily readily induced by suddenly blowing in the child's face, smartly patting it on the buttocks, rapidly rubbing the fingers up and down the sides of the chest, or dashing a small quantity of cold water on the chest. All these means, by irritating the nerves of the skin, stimulate the movements of breathing. In the meantime it is proper not to tie the cord or separate the child from its attachment to the mother. For if the fingers be placed on the cord pulsation will often still be felt, indicating that the circulation in the after-birth has not yet ceased, and there is thus the possibility that the child's blood may still be aerated to some extent through the mother. If the pulsation has stopped, and the child's breathing is not yet established, the cord should be tied, and then divided, and the child's body should be quickly plunged into a basin of warm water, the head of course being supported, and then as quickly removed from it, and cold water plentifully dashed over the chest, then plunged again into the hot water and again the cold dashed over it, till by the sudden changes the breathing is established. If these methods do not speedily produce the desired effect, artificial respiration must be resorted to. The little finger (quite clean) of the attendant should be introduced into the mouth and passed to the back of the throat to sweep out any mucus there. Then one of two methods may be adopted. Dr. Howard, of New York, advises that the child be supported on the attendant's left hand and

arm (as shown in Fig. 189), while the right hand grasps the lower part of the chest. The chest is steadily compressed for three seconds, and then suddenly let go. After waiting for

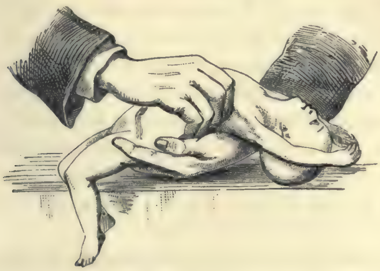

Fig. 189.—Howard's Method of causing breathing in the newly born.

three seconds the pressure is repeated, and so on, ten to twelve times a minute. The second method consists in the attendant, after cleaning the child's mouth, applying his or her own mouth closely to it, and the child's nostrils being closed, gently and steadily blowing till the chest is seen to be inflated. On allowing the nostrils to open the chest will fall again; they should be again closed, and the blowing repeated. This should be continued for a considerable time, at the rate of ten to fifteen times a minute, and if any effort to breathe be made by the child itself the blowing should be timed to aid it.

In ordinary circumstances little effort is needed to excite breathing beyond the slapping, &c., already noted. All that remains to be done, then, is to tie and cut the cord. This is done in the following way. Two pieces of linen thread folded twice, each with a large knot at both ends, are used. One piece is tied tightly round the cord about 1½ inches from the belly, and the other piece an inch further away. The cord is then divided *between the two pieces of thread.* Care must be taken that, in the act of tying, the cord is not suddenly jerked, lest it be torn from its attachment to the belly, which would occasion bleeding very difficult to stop. Further, while the cord is being divided, care must be taken lest the child by a sudden twist brings fingers, toes, or other part between the scissors. As soon as the child is separated from the mother, it is handed over to be washed. This process should be done quickly with warm water, a clean sponge and *a little* good soap. Every part of the body, but especially wherever there are folds of the skin, must be carefully washed, then thoroughly dried, and afterwards *lightly* dusted. Sometimes parts of the body are covered with a white material which soap and water will not remove. Let the nurse rub such parts with oil, lard, or butter till a kind of lather is produced, and then washing will readily remove it.

After the washing the stump of the cord must be dressed. A square piece of linen is employed, the stump is passed through a hole cut in the middle, and the linen is then folded over from above and below, and from each side. It is then *lightly not tightly* secured by the binder. The clothing suitable for the child is given in detail on p. 444, and its feeding on p. 438. It must receive no sugar and water, nor any food except the breast milk.

The Treatment of the Mother after the birth of the child. The first thing requiring attention after the removal of the child is the removal of the after-birth. If the hand has been pressing down on the womb from the outside during the birth of the child, this will probably have aided the separation of the after-birth. The hand is to be again applied on the belly over the womb, which ought to be felt as a firm roundish mass, and if the womb be grasped and gently but firmly pressed downwards and backwards, a slight rubbing movement being at the same time practised, the womb will usually be found to grow smaller and firmer, and to descend. The hand must follow it, the firm pressure being continued, when the after-birth will be readily expelled. *The after-birth is not to be removed by pulling on the cord,* only a gentle pull is to be exerted on it, if the womb is contracted, and merely to aid its expulsion, not forcibly to draw it out. When it appears at the external opening it is to be taken into the grasp of the hand and twisted round and round a considerable number of times. This coils the membranes, expelled with it, into a sort of rope, and prevents any part of them being retained in the womb, to give rise to severe after-pains. After the removal of the after-birth, the hand should be kept pressing on the womb for a little time, and if it show signs of relaxing to any extent by growing larger and rising up into the belly again, slight rubbing will cause renewed contraction, and in a short time it will remain firmly contracted.

The petticoat or other garment which has been round the woman's hips must now be slipped over the legs and pulled out along with the soiled blanket, &c., from under the patient, who meanwhile remains lying on her back, exerting herself as little as possible. A folded and warmed napkin is placed between the legs

to absorb the discharge, the clean warm blanket within a folded sheet is pushed under her, and a bandage applied round the waist. The bandage should be shaped to fit her body and should be fastened with safety-pins in front, a pad of a couple of folded napkins being placed beneath it and over the womb. The bandage is to be fastened with a moderate degree of tightness, and adds much to the person's comfort. The clothing and bed-clothes are now adjusted and the patient left to rest, the head being low.

Soon after the mother has been made comfortable she may have a warm drink, cup of warm tea or such simple drink, *but no stimulant.* It is well as soon as the child is dressed to put it to the breast, if the mother is not too tired, for a few minutes. The contact of the child's mouth with the breast gently stimulates the contraction of the womb, and tends to prevent relaxation of the womb and bleeding. Regularly every third hour thereafter the child must be replaced at the breast (see p. 438), whether there be milk or not. The effort at sucking promotes the production of milk.

If the mother be thirsty a small quantity of cold water or milk is not to be denied her, but only a small quantity is to be allowed. After the first application of the child the woman needs a rest. The infant should be removed to its own basket-bed, in order to permit a two or three hours sleep to its mother. When she awakes she needs food. The old practice was to give only tea and dry toast for several days after confinement, and to deny rigorously all cold drinks. This is absurd, and fortunately is only now practised by the ignorant. The mother needs good nourishing food. It should be provided her in small quantities at regular intervals of three or four hours. It may consist of boiled bread and milk, varied with beef-tea, mutton soup to which only rice and parsley have been added, about a breakfast-cupful at a time with bread, and once or twice in the twenty-four hours a cup of tea and lightly-buttered toast, if such be desired. Diet such as this, if given in moderate quantities at the three or four hours interval, will suit admirably for the first two or three days. During the night the food is also to be supplied. By the third day a soft-boiled egg, switched, and given with bread and milk, will be acceptable, or boiled white-fish, with the cup of tea, beef-tea and soup being also given as before. By the fourth day or thereby the diet may be varied with some well-cooked minced meat or a lean broiled steak or chop, with bread, and piece of chicken and so forth. Thus gradually the diet will return to what is usual, more detailed directions for which are given on pp. 439, 440. Thirst is relieved by small quantities of cold water or milk, soda-water and milk, &c.

If by the third morning after the birth the bowels have not been moved, a sufficient dose of castor-oil should be given. Thereafter, if medicine is required a wine-glassful of Hunyadi Janos mineral water given in the morning is best. Any difficulty in passing water will be relieved by the application of flannel, wrung out of hot water, over the lower part of the belly and between the legs.

Throughout this time the mother remains in bed, not being allowed to sit up for any purpose, food being given by means of a drinking-cup, and the discharges being passed into a bed-pan. *Visitors are forbidden.*

Sitting up in bed is not to be allowed till the seventh day, and then only for a brief period for meals, and the patient must not be allowed out of bed at all before the tenth day, and then only for a few minutes, wrapped in blankets. A fortnight after the birth is soon enough to permit the mother to get up for any length of time with clothes on. Even by that time she should rise for say an hour in the forenoon and an hour in the evening, and each day gradually lengthen the time till after another week she spends the better portion of the afternoon out of bed. It is infinitely better for her to take a long period of rest in order to rise thoroughly recovered and with restored strength, than to get up too soon and require to take soon to bed again with full recovery impeded. Details as to the management of the period of nursing are given on pp. 438 to 448.

After-pains are of the nature of labour pains on a small scale, and are due to irregular contractions of the womb, owing to the presence of blood clots and the effort to expel them. As a rule they do not occur after a first labour, and may be greatly lessened after subsequent labours by the method of following the descent of the womb with the hand, and by the method of removing the after-birth, which have been described. They may be relieved by the application, close up between the legs, of a thick pad of flannel wrung tightly out of hot water. If they are severe a single dose of twenty drops of laudanum may be given. This is to be repeated in two or three hours, only if really necessary.

The discharge from the womb for the first

twenty-four hours after labour is of blood, and contains sometimes small clots. It gradually becomes less red, and by the third or fifth day assumes a greenish or yellowish hue. It has a peculiar odour. It gradually becomes colourless, and finally ceases by the end of two or three weeks. For the first few days the discharge is to be promoted by occasional gentle bathing of the external parts with warm water. Strict cleanliness must be observed, and clean napkins freely employed.

DISEASES OF WOMEN.

AFFECTIONS OF THE GENERATIVE ORGANS.

Diseases of the External Parts.

Eruptions, &c.—The skin in the neighbourhood of the external opening of the genital canal is liable to many of the affections common to the skin in other parts, and such affections may affect the membrane lining the entrance to the passage.

Thrush, for example, such as occurs in white patches in the mouths of children, is not infrequent. Refer to page 460. The treatment described there is to be adopted.

Herpes (p. 317) is also found. It soon disappears if kept smeared with vaseline or zinc ointment, and if cleanliness be exercised.

Inflammatory Blush (p. 313), due to irritating discharges or the rubbing of opposed surface, is to be treated by bathing with warm water, then drying carefully, and dusting with oxide of zinc powder.

Erysipelas is to be treated as advised on p. 314.

Eczema (p. 318) is usually due to irritating discharges, to dribbling of urine, and is frequently the result of diabetes (p. 303). It occurs in very fat women, who perspire freely and are not sufficiently given to frequent bathing. It may spread from the inner surface of the passage outwards over the skin, down the thighs, and up over the belly, and round to the opening of the bowel. The surface is red and leaking, crusts form owing to the drying of the discharges, and bleeding cracks are produced. The parts are extremely sore and smarting, and painfully itching. The intolerable itching causes frequent scratching, which tears the tender surface, causing it to bleed. The main part of the treatment is scrupulous cleanliness. The parts should be bathed several times a day with warm water, and some mild soap—glycerine or tar soap. Any discharge from the passage, or any other apparent cause, must, of course, be got rid of. Bathing with warm lime-water, or warm water to which a pinch of carbonate of (baking) soda is added, relieves the itching. An ointment may then be used made of oleate of zinc (60 grains) and vaseline (2 ounces), or oleate of bismuth (60 grains) and vaseline (1 ounce), or chrisma sulphur. In the absence of these the ordinary oxide of zinc ointment, made with vaseline instead of lard, will do; or a wash made of glycerine (1 ounce), borax (60 grains), and rose-water (1 ounce). Should such measures fail the person must consult a doctor, lest diabetes be at the root of the trouble, or some irritating condition of the urine.

Warts, of a soft kind usually, are found just at the opening of the passage or just within. Sometimes they exist in great numbers. They may be removed by the use of glacial acetic acid, very carefully applied. The top of the wart alone is touched, and the application is repeated daily till it disappears. The patient herself should not attempt to apply it, as she will certainly be unable to prevent the acid running on to sound skin. Besides this, the part should be frequently bathed, dried and dusted. Any discharge should be treated.

Growths, called **tubercles**, much larger than warts, also occur. They require skilled treatment.

Sensitive Red Patches are occasionally found just within the entrance of the passage. They may be associated with small, red, sensitive growths round the opening of the urinary passage. They occur about the time of the change of life; they occasion much distress, and are very difficult of treatment. It is almost useless to mention treatment here, but any irritating discharge should be removed, if possible, and strict cleanliness should be observed. Some dry cotton wool inserted just within the passage will make walking more easy, and at bed-time a plug of wool, soaked in a solution made of equal parts of glycerine and neutral acetate of lead, will relieve pain. Any of the sensitive growths referred to require the aid of a surgeon for their removal.

Itching of the Genitals (*Pruritus*).—This is often a most distressing complaint. The itching is intense, accompanied by burning heat and tingling. It is commonest in women advanced in life, though it also occurs in the young. The itching is usually aggravated by warmth,

and thus the suffering is most intense shortly after the person gets warm in bed.

It is not necessarily accompanied by an eruption, though it is the companion and effect of such a disease as eczema, referred to on the preceding page; but it may exist, to begin with, without any eruption or any appearance of change in the skin whatever. But as a result of the scratching, from which the patient cannot refrain, though it is painful, cracks, scratches, &c., are produced, which bleed, and with the continual scratching may become themselves painful, and lead to the formation of scabs, crusts, &c. This, however, is not the cause but the result of the itching, in this particular instance.

Treatment.—Such itching as has been described is not to be regarded as a disease in itself. It is to be looked on rather as a sign of disease, and its true cause must be searched for and found, if it is to be satisfactorily treated.

A common cause is diabetes (p. 303). The writer has seen several cases of this most annoying itching in elderly women, for which no washes or local applications afforded more than a temporary relief, and which had existed more or less for months, and in one case a couple of years, the cause of which showed itself at once on an examination of the urine, and which disappeared very soon after diabetic treatment (p. 303) was resorted to.

The presence of a constant irritation is another frequent cause. The irritation may, however, be of many varied kinds. It may arise from a discharge of whites or other discharge from the womb or genital passage, or the watery discharge of cancer; it may be due to some condition of the urine, excessive acidity, the presence of oxalates (p. 302), stone in the bladder, or worms in the bowel, or, and this is not to be overlooked, it may be the result of the work of the particular kind of louse found in this region (p. 325).

A variety of other conditions may occasion it,—a gouty or rheumatic state of body, various unhealthy states of the womb, &c. &c. Besides all these, it would appear sometimes to be due simply to a condition of over-sensitiveness of nerves of the part.

Each cause has its own appropriate method of treatment, and it will usually require the skill and patience of an educated medical man to determine what that cause is, and what the proper treatment ought to be. Without such advice, the patient should try the effect of frequent bathing, and syringing with tepid water, to which a pinch of common baking soda may be added, the parts being dried after the bathing, and then lightly dusted with white oxide of zinc powder. A lotion made of 60 grains of the acetate of lead to 2 ounces of water is very soothing, or a lotion of 1 grain of bichloride of mercury to 1 ounce of water may be tried. The latter is very poisonous, and the bottle containing it should be carefully labelled and kept out of the way, lest accidents happen from mistaking it for something else.

Inflammation round the external opening is called *Vulvitis*. It is not seldom met with in infants and young children. Want of cleanliness may be the cause, or injury, and it is not necessary to suspect contagion from the child being ill treated, though, of course, such might be the cause. The parts are red, swollen, painful, itching, and from them flows a mattery discharge. If there is much pain and redness, soothing poultices should be applied, warm bread poultices or warm poultices of boiled mashed turnips. If the parts are not acutely inflamed bathe first with lukewarm water, and then with a lotion made of 20 grains of sulphate of zinc to 10 ounces of water. A gentle purgative of calcined magnesia or effervescing citrated magnesia is useful, and good nourishing food must be given.

Boils and Abscesses form in this region. Soothing poultices must be applied, and any matter present must be removed. This requires a surgeon. Proper advice is all the more necessary, as a rupture (**hernia**, p. 191) occurs here in female children, and must not be mistaken for an abscess.

Diseases of the Vaginal Passage.

Inflammation extending, that is, beyond the mere entrance up into the canal, is called properly *Vaginitis*.

Its **cause** may be very various—want of cleanliness, irritation of worms which have passed up the canal from the bowel, the presence of foreign bodies, such as a pessary introduced for a displaced womb, &c. Simple exposure to cold, especially at a monthly period, seems capable of producing it. It occurs, also, in the course of diseases like measles, small-pox, scarlet fever, and is more apt to be found in persons of depressed general health. Irritating injections may be its cause, and it may be the consequence of direct infection.

Symptoms.—The passage is hot and tender,

there is a sense of burning and smarting, bearing-down pain, frequent desire to make water, and pain in passing it; aching and throbbing are felt in the passage, and walking is attended with difficulty. The external parts may also be swollen and inflamed. There is also discharge, at first of clear and then of yellowish matter, which is often badly smelling. After a sharp attack the inflammation may pass off in a few days or weeks, or it may become chronic in persons whose vital powers are depressed.

Treatment.—In the period of acute inflammation the person should be kept at rest in bed; brisk saline purgatives, seidlitz-powders, or effervescing citrate of magnesia, should be given, and mild food, milk, soups, &c. *Stimulants must not be given.* Without skilled advice hot hip baths may be given, or injections of water as warm as can be comfortably borne. The injection should be given with an enema syringe (Higginson's or Davidson's, see Plate VIII.). The nozzle should be of caoutchouc, five or six inches long, and several openings should exist *round the extremity of the nozzle, not one at the very point.* The person should lie on her back, with the hips raised. The water should be injected *slowly*, and care must be taken that it escapes quite easily. From a half to one gallon of water may be used at one time, and the injection may be repeated twice or thrice daily in sharp attacks. After the injection a medicated pessary of 3 grains extract of belladonna should be pushed up into the passage and allowed to remain. It gives great relief. When the acute stage is past an injection of 30 grains sulphate of zinc to 1 pint of water is to be used. At the same time any bad state of general health requires treatment if the disease is to be got rid of.

Discharges from the passage (*Whites, Leucorrhœa*).—The lining membrane of the passage is studded with minute glands, which produce a clear thickish fluid for keeping the parts moist. Under a variety of circumstances it is so increased in amount as to appear externally as a discharge. Just as when one has cold-in-the-head, or catarrh as it is properly called, the minute glands studding the lining membrane of the nostrils pour out their discharge, which ordinarily is simply sufficient to keep the nostrils moist, and there is in consequence a "running at the nose," so, as the result of exposure to cold or damp, the genital passage may be affected with catarrh and the discharge appear. It may be thin and milky in appearance, or thick and sticky, or yellowish. Commonly it is whitish, and has, therefore, been called "the whites." Besides being the result of cold, it may occur as a symptom of depressed health, in pale delicate girls for example, as an expression of defective nourishment. It may also be a consequence of prolonged nursing. The discharge may originate, not in the passage, but in the womb itself, and may be the expression of some disorder there. In pale, weakly girls such a clear discharge may occur at the monthly periods without any discharge of blood. It will be the constant attendant of chronic inflammatory conditions of the passage.

The subject of such a chronic discharge usually complains of backache, discomfort in the lower part of the belly, and general weakness. This weakness may itself be the cause of the discharge, but the occurrence of the discharge will make the weak state of health all the worse.

Treatment ought to be directed to the cause of the disorder. In states of bad general health efforts must be made to improve the general health. For such a purpose the bowels must be regulated, preferably by such a gentle medicine as a mineral water, for example a wine-glassful of Hunyadi Janos each morning. A moderate amount of exercise should be obtained daily. Overwork of every kind is most injurious, whether in the case of the married woman who has a house and children to look after, or in that of the girl who has some business occupation in the workshop, warehouse, office, or school, or in the case of the girl going in for the higher education. Easily digested, nourishing food is essential. Change of air and sea-bathing are very valuable, and quinine and iron tonics ought to be administered. In the way of direct treatment to the parts the person should restrict herself, failing advice, to simple measures. Warm-water injections, and injections of a lotion of sulphate of zinc (2 grains of sulphate of zinc to 1 ounce of water), are useful, or injections of iron-alum of the same strength. If the discharge be irritating, an injection of a lotion containing ½ ounce of carbonate of soda (baking soda) to 1 pint of water, affords great relief. If such measures fail competent advice must be obtained. Indeed, where at all possible, such advice ought to be obtained from the commencement, as the inflammation may extend up into the womb and onwards to the ovaries, or to the bladder, and lead to very serious consequences.

Fistula implies the existence of some unusual communication between the genital passage and the lower end of the bowel on one side, or between the genital passage and the urinary bladder on the other. The former is called **recto-vaginal fistula**, and the latter **vesico-vaginal fistula.** The commonest cause of both arises in the course of labour. It may be that the rent occurs in the process of delivery, either with or without instruments, from the narrowness of the passage and the want of stretching capacity, or from the size of the child. In such cases it is commonly the partition between the genital canal and the bowel that gives way. It may result from long-delayed labour, when the head of the child becomes fixed and long-continued pressure is maintained upon some part of the walls. In such a case it is usually the division between the passage and the bladder that yields. Part of the wall has become so damaged by the pressure that some time after delivery, a day or two or a week or two, it separates and comes away as a slough, leaving an opening, through which the urine from the bladder finds its way into the passage. While the former misfortune may occur even with the most careful and skilled management, the latter is commonly the result of mismanagement, undue delay having been allowed to occur in the use of instruments or other means of hastening delivery. The same unusual communications may be opened up by the bursting of abscesses, by prolonged ulceration, by destruction of parts owing to cancerous disease, by wounds, and so on. But there are less frequent causes than those above mentioned. In the case of the opening between the bowel and passage, matters from the bowel will be passed by the genital opening, and in the case of communication with the bladder, urine will dribble away in an unusual manner. Other results follow. The presence of discharges in the genital passage foreign to it almost certainly occasions some degree of inflammation, extending to the external parts, which become inflamed and ulcerated, and occasion much misery by their constant smarting and itching.

Treatment of such conditions have become much more hopeful in recent years, due mainly to the skill of American surgeons Emmet and Marion Sims. The treatment consists in an operation for reuniting the edges of the tear. It is, of course, in cases where the rent is comparatively simple, as in those arising during childbirth, that the treatment is likely to be adopted, and not in fistulæ the result of cancerous ulceration.

Tumours and Growths of various kinds may occur in connection with the external parts of the genital organs or in connection with the genital passage. An **abscess** may form on one side of the external opening large enough to block the opening, and may appear to the unskilled as a solid growth instead of a mere collection of matter. Such might occur as a result of inflammation, or from some slight blow or bruise, or even from such a slight cause as the tearing out of a hair. In a similar situation there occurs, though rarely, a swelling due to a **rupture** (*hernia*, see p. 191), a loop of bowel passing down from the abdomen into a position similar to that which it occupies in the male. To mistake this for an abscess would be very serious indeed. It can be reduced and prevented from returning by the use of a properly fitting truss.

Cancer occasionally occurs on the external parts, in the form of skin cancer (see p. 434). Within the passage itself cancer does not often occur, unless it extend inwards from the outside, or downwards from the womb. When it is present, pain, bleeding, and a foul discharge are among its usual signs, but nothing is conclusive apart from the opinion of a competent medical man, who has made a thorough examination.

All sorts of **foreign bodies** have been found in the passage, which have been passed in accidentally or by design. It is not uncommon for a doctor to have to remove a pessary, inserted for treatment of displaced womb, which has remained there for years, forgotten by the patient, and has become almost fixed in the parts, in the end producing inflammation, discharge, &c. The removal of such bodies should be attempted only by skilled hands.

Diseases of the Womb.

Inflammation of the womb is a very wide term, embracing a variety of diseases known to medical men under special names, and requiring special treatment. It will be sufficient here to indicate the general features which the various forms of the disease have pretty much in common, and the general lines of treatment which can be safely adopted when medical aid is not readily obtainable. If reference be made to page 479 the distinction will be understood between the body of the womb and the neck

of the womb, which latter ends at the mouth, opening into the genital passage. Inflammation, then, may attack both the body and neck of the womb, or it may limit itself to one or other. Further, the womb is largely composed of muscle, but, within, it is lined with a mucous membrane, containing glands buried in it and opening on the surface (inner). The inflammation may exist mainly in the muscular walls, or it may be limited to the inner lining membrane. Thus there may be inflammation of the muscular walls of the *body* of the womb, or inflammation of the lining membrane *of the body* of the womb, and there may be inflammation of the muscular walls of the *neck* of the womb, or inflammation of the lining membrane of the *neck* of the womb.

Here are, then, four varieties of inflammation. Moreover, in each of these four cases the inflammation may be acute or chronic, and so there may be eight forms of inflammation of the womb. The symptoms, while presenting similar general features, will vary somewhat with each separate condition, and the treatment, to be thorough, ought also to vary somewhat to suit the particular case. The extreme advisability, therefore, of any one suffering from any of the symptoms of disorder of the womb, consulting a skilled medical man, ought to be sufficiently plain.

Happily the inflammation of the muscular walls, whether of body or neck of the womb, may be dismissed with the remark that they are comparatively rare. The common form, and it is, in its chronic form, extremely common, is inflammation of the lining membrane *of the neck* of the womb, and to that attention shall be confined, note being taken in the course of its description of any symptom indicating that the inflammation has spread upwards to the lining membrane *of the body* of the womb.

Symptoms.—The common symptoms of inflammation of the lining membrane of the neck of the womb, when not of an acute form, are profuse discharge of whites, some amount of pain in the small of the back, worse with standing or walking and increased at the monthly periods, and a sense of indifferent general health. If the disorder has lasted for a considerable time the patient will of necessity suffer from general debility to a greater or less extent, and will be paler than is consistent with health. Her digestion is almost certainly disturbed, and she may suffer from depression or nervousness, and a variety of pains and aches, now in one part of the body and now in another. The bowels are probably confined, and the urine is dark and thick. The discharge that appears externally may be glairy and clear, like white of egg before being boiled, or may be white or yellowish matter.

If the attack be acute there are pain and tenderness in the parts, throbbing with a feeling of bearing down, irritation of the bladder and frequent desire to pass water, and the discharge is often tinged with blood and of an offensive smell.

It is to be noted, however, that inflammation may exist for some time without pain, or any other symptom, except that of a profuse discharge of "whites."

Causes of the disease are numerous. Exposure to damp and cold, especially in those of feeble health, insufficiently nourished, and who fail to obtain sufficient exercise and fresh air, the irritation of a displaced womb, or instruments introduced into the passage to restore a displaced womb to its proper condition, the frequent use of irritating injections, and various other causes may produce it. It is excessively common in married women who have borne children, and too prolonged nursing may with them excite its occurrence. Nor must excessive intercourse and direct infection be omitted in the list of causes.

The condition of the parts is very much that of an inflamed and swollen throat. The lining membrane is swollen and congested, and the discharge proceeds from the glands which exist in it in enormous numbers, just as from a swollen and inflamed throat there proceeds excessive "defluxion."

The inflammation of the lining membrane of the body of the womb is attended by discharge similar to the other, but in greater amount, and disturbances of the monthly illness—irregularity, excess, or diminution—are more common. Marked nervous symptoms are often produced by it. The person is fretful and despondent, may suffer from frequent headache, limited to the top of the head, and from other pains resembling neuralgia, and the dragging pain in the back is very marked. But any difference in symptoms is rather one of degree than of kind.

A not uncommon cause of this condition is sudden stoppage of the monthly flow from cold and the irritation of matters retained in the womb after confinement or miscarriage.

Treatment.—What has been said about the causes of this disease is sufficient to show that there can be no rough-and-ready or "rule-of-

thumb" procedure in dealing with it. If the condition be mainly caused by a bad state of general health, it cannot be supposed that applications to the affected parts will cure it while the general bad health remains. Even though such a cause has not been at work in its production, the disease cannot have lasted any time without inducing some degree of bad health, which will stand in the way of a cure. Then if a displacement of the womb is the cause of the inflammatory process, nothing short of restoring the organ to its proper position can be expected to promote a permanent recovery. A mother who suckles her child beyond the necessary period, and suffers from some disorder of the womb, cannot expect to cure by injections what is maintained by the drain upon her system of prolonged nursing. So with other causes. Now, it would be the business of a medical man, well acquainted with such conditions, to determine the cause at work in each particular case, and to apply his treatment accordingly. It is plain, therefore, that it is really quite impossible to state any definite plan of treatment which a patient might herself adopt with good prospect of recovery from her trouble. The best advice that could be given would be to place herself under the care of a physician from whom she might confidently hope to receive skilful and conscientious treatment. At the same time it is only right to state some simple means of treatment which a patient may herself adopt, when skilled advice may be for the time beyond her reach,—some means which cannot be hurtful no matter what may be the exact cause of the disorder, and which will give some relief in most cases, and in some may be sufficient for a cure.

The first thing, then, to be done is to restore, if possible, a good measure of general health. The means to that end are, good food of sufficient quantity and easily digested, the regulation of the bowels, avoidance of overwork and excitement of any kind, a fair amount of exercise, exercise short of fatigue, and plenty of fresh air—sea-air is specially beneficial. Concerning food the mistake must not be made of living on slops, corn-flour, arrow-root, and foods of that kind mainly. Milk should bulk largely in the diet, but also other animal foods, soups, eggs, fish, and a fair daily supply of butcher meat. A great many women make a grievous mistake in avoiding as much as possible such animal foods, and half-starving themselves on sloppy diet. For the regulation of the bowels nothing is better than a wine-glassful or thereby of the Hunyadi Janos mineral water taken the first thing in the morning. Over and above this some quinine and iron tonic will be of much value in depressed states of health.

As regards applications to the affected parts one thing can be very strongly advised, namely, the use of hot water injections. To obtain the full benefit they must be given in the way to be described. The patient lies across the bed, a pillow under the back to raise the hips, the feet resting on chairs. A piece of mackintosh cloth is placed under her, and arranged to cause water to flow off into a pan at the side of the bed. The injection is given by some one assisting her. About one gallon of hot water should be used, water comfortably warm to the hand, by the thermometer about 110° Fahrenheit. An enema syringe is employed, with a nozzle of vulcanite or similar material, about 6 inches long. The end of this tube should not have a single opening at its point. It should end in a blunt form, and several openings should exist round it. The syringe being properly filled and in good working order, the nozzle is oiled and passed into the passage gently near the back wall and directed backwards. It should be passed in as far as it can easily slip, and then the water should be steadily and slowly injected. Owing to the hips being raised the passage will become filled with the hot water before any flows out, and this is what is desired by the method. At the same time care must be taken that there is no obstacle to the free escape of the water as soon as it has filled the passage. The injection should be given in this way at bed-time, every night or every second night. A little patience will render it comparatively easy, and the patient will speedily discover the ease and comfort it affords. If there is any insuperable difficulty in giving it in this way, the patient must content herself by using the enema syringe while she sits over a pan or bath, but the water should be used at the same heat and with the enema, the nozzle being passed well in. If the patient is very anxious to try some medicated injection, any of those mentioned on p. 499 may be employed, after the hot water, but their use is not to be persisted in for long periods if they fail soon to give relief.

Ulceration of the Womb is a phrase that strikes terror to the ears of most women. It used to be far too commonly employed, and is probably still. The condition which it is frequently used to signify is practically that already described. Owing to chronic swelling the

inner wall of the neck of the womb and its mouth become thickened, prominent, and too freely supplied with blood, but in the vast majority of cases to which the name is given there is no such eating away of the substance of the part as the name would imply.

The **treatment**, so far as the patient can resort to it, is such as has been described under inflammation. One other thing she may be able to do, and that is, take a little ball of cotton or lint, soak it in glycerine, and then push it up the passage as far as possible. *She must be careful to remove it next day or within two days*, and after syringing with warm water may replace it by a fresh one. If it is difficult of removal syringing will readily bring it down. A medical man would employ further treatment by directly painting the affected part with one or other of a variety of applications.

Tumours of the Womb.—Three forms of tumour of the womb are of comparatively frequent occurrence, namely, **polypus, fibroid** or **fibrous tumour**, and **cancer**. There is one broad distinction between the two former of these and the latter, and that is, that the two former are simple tumours, formed of overgrowth of some part of the substance of the womb, not destroying the substance and not necessarily dangerous to life; while the latter is a growth foreign to the true substance of the part, invading and destroying it, and tending inevitably to death within a comparatively limited period.

The **polypus** varies in size from that of a small pea upwards, and may be an overgrowth of the lining mucous membrane, or an overgrowth of the wall beneath the lining membrane. It projects into the cavity of the womb, being connected to its walls by a longer or shorter stalk. By its presence a polypus causes a greater determination of blood than is proper to the womb, and thus gives rise to bleeding, especially to excessive loss at the monthly periods. It also excites contractions of the womb, and so occasions painful spasms and pains in the back and loins. It may block the opening of the womb, and by causing difficulty of escape of the monthly discharge cause the illness to be attended by severe pain.

The **treatment** is surgical, and consists in the removal of the polypus.

The **fibroid tumour**, fibrous tumour, or fibromyoma, as it is also called, may occur in various situations, and may be of a great variety of size. It is a simple overgrowth of part of the wall of the womb. It may project into the cavity of the womb like a polypus, or it may project in the direction of the outer wall towards the cavity of the belly, or it may remain embedded in the substance of the wall, difficult to distinguish from simple enlargement of the womb. In size such tumours vary from that of a pea to that of a human head. They are extremely common, but may exist without giving any indication of their presence. They rarely appear before the period when the monthly illness begins. Their growth is encouraged by the regularly recurring increase in blood supply to the womb by the monthly illness, and also by the stimulus of sexual excitement. Marriage will thus tend to stimulate the growth of one already present, while the presence of one may be a cause of sterility: the fact of sterility will also encourage the growth. As a rule they cease to grow when the child-bearing period has passed, and thus if this age is reached a woman troubled with such a tumour may look for a gradual relief from its symptoms.

The **symptoms** are of two kinds: (1) those due to the mere pressure of the growth on surrounding parts, the chief of which is pain; and (2) those due to the increased blood supply to the womb which the tumour occasions, of which the chief is excessive loss of blood during the monthly illness, or a more or less continuous loss of blood.

The pain may be of a spasmodic character due to the tumour stimulating contractions of the womb, or it may be of a neuralgic form due to pressure on nerves, or it may be a dragging pain in the back and loins, a constant wearied feeling, easily increased by walking, and also by carriage exercise when the tumour is of any size. Other pressure symptoms may exist, such as confirmed constipation from pressure on the bowel, frequent desire to make water or inability to make water, or pain in making it, swelling of the legs, &c., and such symptoms are all liable to be aggravated at the monthly period owing to the increased size of the womb at that period. Then the monthly illness may be attended with great pain owing to the tumour blocking the escape of the discharge, and the presence of the tumour also occasions not unfrequently great pain during sexual intercourse.

Excessive flow of blood may not be marked in cases where the tumour is embedded in the walls of the womb or bulging towards the cavity of the belly, but is likely to be the main symptom when it bulges towards the cavity of the

womb itself. Usually it is a prominent symptom, and, as has been said, the loss of blood may not be limited to the period of the monthly illness, but may go on almost without ceasing. The loss of blood may be so excessive as to become the grave feature of the case.

Treatment.—It is to be remembered that the tumour is a simple one, in no way to be regarded with apprehension such as a cancerous tumour would excite. It may be a constant worry and cause of suffering from pain, &c., but it need not prove fatal. The loss of blood occasioned by its presence is the serious part of it, since this may threaten life, either directly or by exhaustion, or by laying the patient open to other disease from the general bad health arising from it. The object of treatment is to relieve the symptoms as much as possible till the child-bearing period is past, when a gradual cessation of the patient's trouble is likely to ensue.

The tendency to lose blood may be restrained by avoiding everything that would increase the blood supply to the womb. As much rest as possible during the monthly illness is, therefore, desirable, and if the patient be married restraint as much as possible from the exercise of sexual functions. Pregnancy might be a serious complication, though occasionally a fibroid tumour has almost or entirely disappeared after pregnancy and a successful confinement. Unmarried women should remain so if they are aware of the existence of such a tumour. Just before the monthly illness opening medicine in the form of mineral water or effervescent citrate of magnesia is beneficial, and nourishing but unstimulating diet, with avoidance of spirituous liquors, should be the rule.

If the bleeding be excessive the effort to limit it should be made by taking the liquid extract of ergot, from one half to a whole tea-spoonful in water thrice or four times daily; and if excessive loss of blood during the period has been the rule, this should be taken for a day or two before the illness begins, and for a few days after it has ceased. To relieve pain a pill of one-third of a grain of extract of Indian hemp may be occasionally taken, or 30 grains of bromide of potassium dissolved in water. Iron tonics taken during the intervals are valuable for restoring or maintaining the general health. Pain is often also relieved by the use of some support to the uterus in the form of a pessary if such can be adjusted for the purpose.

If the loss of blood be so excessive or persistent as to threaten serious consequences, a surgeon would probably propose an operation for the removal of the ovaries. The ovaries being removed, the monthly illness ceases, and thus nature's method of relieving the patient is anticipated.

Cancer of the Womb.—This disease may occur in the body of the womb or be limited to the neck (p. 479). The former case is comparatively rare. Cancer differs from fibroid and other simple tumours, in that it destroys the substance of the organ in which it is situated, spreading through it and from it to other parts, and tending also to pass to other organs. If it be removed it is liable to return. For these reasons a cancerous tumour is called malignant as opposed to simple. The womb is the commonest seat of cancer in the female, and its occurrence there is very frequent. It rarely occurs below the age of twenty years or above that of sixty, and is most frequent between forty and fifty. It has an inevitable tendency to death, and from one to two years is the average period of life after its appearance.

Its **cause** it is impossible to state. That it has a tendency to occur in families seems undeniable, and some distinguished authorities believe it occurs chiefly in women who have borne children, and in whom the neck of the womb has been torn. Such local irritation, however, may be only the exciting cause of the appearance of a tumour to which the woman was already disposed.

There are several varieties of it. It is common as an affection of the lining surface of the neck of the womb, gradually eating into and destroying the deeper parts, occasioning ulceration and thickening extending inwards.

Its **symptoms** are mainly pain, loss of blood, and discharge. The pain may not arise till the disease is far advanced, and is of a stabbing or burning kind, shooting up to the loins and down the thighs. It is generally worse at night. It is the loss of blood that often arouses suspicion. It may occur from apparently trifling causes, and though it may be slight to begin with, it becomes at length a perpetual drain upon the body. As a consequence the person comes to have a characteristic appearance, the skin becoming of a peculiar sallow or dirty yellowish colour. The discharge is watery, tinged usually with blood, extremely irritating to the skin of the external parts, and of a very offensive smell. The disease may ulcerate its way into the bladder or bowel, so that water constantly dribbles away or motions are passed from the genital passage.

The whole system becomes affected and deranged, and if death does not occur directly from loss of blood, exhaustion is frequently the consequence.

Treatment.—If the disease be detected early enough, its removal by the knife may effect a cure, or at the least will for a season stop suffering and prolong life. Many methods of cure by medicines have been praised at different times, but all have been in the end found comparatively useless.

The foul discharge may be relieved by the injection with the enema syringe of water containing 10 grains of thymol to the ounce, or of a 2½ per cent solution of carbolic acid.

To relieve pain opium in some form is the remedy. But it should be used under medical advice.

Everything possible should be done to maintain the patient's general health by plain nourishing food, the use of iron, quinine, and similar tonics, and the regulation of the bowels by such gentle medicines as a mineral water. Stimulants should be avoided as far as possible.

Displacement and Falling *(Prolapse)* of the Womb.—Displacements of the womb are exceedingly common, commoner than is generally supposed, frequently existing without giving rise to any marked symptoms. At the same time the displacement may give rise to many and pronounced symptoms, which no treatment does anything to relieve except that of replacing, as nearly as possible, the womb in its original position.

The womb is suspended, as it were, in the middle of the pelvic cavity (p. 22) with the bladder in front of it, and the termination of the bowel behind it. It is maintained in its position by its attachment to these organs, and by bands or ligaments of its own, and in its situation is freely movable in various directions. The upper end of the body is directed upwards and forwards, and the mouth downwards and backwards, so that, when the person is in the erect position, it may be said to incline forwards.

Now it may not be maintained at its ordinary level, but sink somewhat *downwards,* for example, because of enlargement or congestion rendering it too heavy for its supports, or because the supports have become stretched and weakened. This is called **prolapse,** and will vary in degree according as the womb sinks lower and lower. If it sink greatly the mouth of the womb may appear at the external opening, and, in very extreme cases, it may appear entirely outside, which form is called **procedentia.** It naturally will drag down with it the wall of the bladder to which it is attached in front, and the wall of the bowel to which it is attached behind. Further, instead of being inclined forwards, as in the ordinary position, it may be tilted backwards, in which case the body looks backwards and the mouth forwards, and this backward tilting also varies in amount. **Retroversion** is the name applied to this displacement. Or the womb may be *bent* backwards on itself, so that the body of it is directed backwards, the mouth maintaining pretty nearly its proper position. It is doubled on itself. This is called **retroflexion.** Again the *forward* slope may be exaggerated, so that the womb tends to lie across the cavity. This is **anteversion;** or it may be *bent forwards* on itself, which is called **anteflexion.**

The **causes** of such altered positions are numerous. Congestion, overgrowth, the presence of tumours, &c., adding to the weight of the organ, tend to displace it. A very common cause of this kind arises when a woman begins to go about too soon after a confinement. The womb has not had time to return to its natural size, and its supports, stretched and weakened by the pregnancy, are unable to bear up the unusually heavy womb, and thus it assumes an improper position. General ill-health may so diminish the vigour of the supports and diminish the tone of the womb itself as to occasion a "displacement." Further, any undue pressure may force it out of place, and if this be long continued it does not get a chance of returning to its natural place. Undoubtedly a great cause of such pressure is the undue weight of clothes and tight lacing. These diminish the size of the belly cavity by pinching in the waist. The bowels are pressed upon, and to find room press downwards on the womb, &c., forcing it out of position, and *keeping it out of position.* The pressure of a tumour in the belly may act in the same way. A tumour pressing upwards from below may also displace the womb, but in a different direction. As another example, the frequent existence of a distended bowel or overfull bladder, apt to occur in women, may occasion it. Undoubtedly falls, violent exertion and such agencies are often at work in producing such disturbances of position. In women who have borne children, the womb is often deprived of its due support from below by rupture of parts during labour, and it is then apt not to be duly maintained in proper place.

It ought, also, to be noted that a womb, dis-

placed from any cause, is liable to be the seat of congestion and other disorders, because of the disturbance to the proper circulation of blood through it which the displacement occasions, and such congestion will then tend to increase the departure from the natural situation.

Symptoms.—Unless in cases of prolapse, where the mouth of the womb appears externally, there are really no symptoms, by which a patient could decide for herself the nature of her trouble. There are likely to be many which would lead her to conclude that something was wrong with the womb, but none which would enable her to conclude what was the real nature of that something. The existence of a displacement and its kind can only be determined by a skilled medical man, after he has made an examination by introducing his finger into the passage, and thus ascertaining the position of the organ.

The symptoms that point to such uterine trouble are back-ache, pains in the loin, discharge, perhaps pain at the monthly illness. A womb displaced backwards is liable to press on the bowel and cause constipation and piles; a womb displaced forwards is more apt to give rise to bladder troubles, pain in making water, frequent desire to pass water, &c. &c. There is often discomfort or difficulty in walking. Indigestion is extremely common and persistent, and is sometimes the only result of a slight displacement. Indigestion so caused is almost certain to defy any treatment directed to it, but speedily disappears if the displacement be detected and got rid of. Sterility is common in all forms of displacement, but particularly in those in which the uterus is bent on itself, for the bend blocks the canal of the womb and prevents the passage upwards of the seminal fluid. Further, nerve troubles are in many cases the main pronounced symptoms of such disorder, which, like those of digestion, defy all treatment unless the uterine condition be attended to. Such disturbances of the nervous system are more apt to occur in young unmarried girls; and the hysterical condition into which young excitable girls are sometimes brought by such a cause is not easily overcome.

The **treatment** of such conditions is in many cases not attended with much difficulty, while in other cases it is by no means easy. In all, as a general rule, very great relief can be afforded, even though a permanent cure is not obtainable. But the treatment can only be properly undertaken by a medical man. It consists in restoring the womb to its natural position, if that is possible. Sometimes it is not possible, because of the very long duration of the displacement having caused the womb to become fixed in its altered position, or because of inflammatory adhesions binding it down. It is very often possible for the surgeon to replace the womb simply with the fingers, and more often with the aid of a long slender rod, on a handle, called a sound, the use of which, in skilled hands, ought not to be attended with any considerable pain. The second element in the treatment consists in the introduction into the passage of a small instrument, called a pessary, made commonly of vulcanite, but also of celluloid, or india-rubber, in the shape of a large ring, which is so placed as to support the womb in its restored position. The shape of the pessary varies with the kind of displacement. If it is properly adjusted, it should occasion no inconvenience whatever, the patient should, indeed, be unable to perceive its presence, and it does not require any alteration in ordinary ways of life, does not, for example, necessitate a married woman living a single life, while it remains in the passage. The third element in the treatment consists in the endeavour to restore vigour and tone to the parts, so that in course of time the pessary may be removed with some hope of the womb remaining in its restored position. Such treatment necessitates attention to the bowels, to the food, to proper exercise, fresh air, &c. Tonics will aid the endeavour. But the suitable tonic depends on circumstances to be judged by the physician.

Anyone who is wearing such a pessary ought to return from time to time to her medical attendant, and ought to see him without delay if any signs of its presence irritating the passage arise. Probably the pessary will require to remain six or eight months, but it ought not to remain longer without the medical man's sanction. Patients have been known to forget altogether the presence of the instrument, and to continue wearing it for very prolonged periods, till it became fixed, impacted by incrusted remains of discharge, urinary sediment, &c.

While the instrument is being worn, frequent use of the injection by an enema ought to be persisted in. This will not only aid in restoring the vigour of the womb and neighbouring structures, but by the constant cleanliness will prevent irritation arising from the presence of the pessary. The daily use of the injection is strongly urged. The injection had better be not of warm water only, but of warm water with some added carbolic acid, of a strength

equal to one ounce of the acid to every two and a half or three pints of water. The pessary is simply to be regarded as affording a mechanical support till the womb is restored to its natural condition.

The form of displacement most readily treated by pessaries is the backward displacement, the backward tilting of the womb, and happily this is the commonest of the displacements. The forward displacement is much less easy to treat in this way, from the difficulty of adapting an instrument to this situation. Fortunately it is not nearly so common a form.

Some cases of prolapse are readily benefited by treatment on these lines, others are extremely troublesome. Recently for the most aggravated cases of prolapse, an operation has been adopted by Dr. Alexander of Liverpool, which has yielded good results. It is not a serious operation, and by it the ligaments of the womb are pulled upon and tightened, "the slack is pulled in," so to speak, and the womb thus restored to its proper height and held there. Tonic treatment is necessary to restore a good condition of general health, so that, when the instrument is removed, the womb may keep its position by its restored vigour.

Diseases of the Ovaries.

Inflammation of the Ovaries and Ovarian Pain (*Neuralgia*).—Inflammatory diseases of the ovaries are not easily separated from similar affections of neighbouring parts. Moreover, the ovaries share in disorders of the womb and in diseases of parts in their neighbourhood, the removal of which will usually be accompanied by the cure of the ovarian disorder.

Any cause tending to induce congestion of organs in the lower part of the belly will produce congestion to a greater or less extent of the ovaries and set up symptoms specially referred to them. Thus sudden stoppage of the monthly flow is such a cause, and inflammation occurring after child-birth.

The **symptoms** that point to the ovaries are pain, sometimes excessively severe, in the region of one or both ovaries, that is about the middle of the groin. The slightest pressure in this position is very painful. In chronic cases of inflammation the pain is constant and wearing, usually worse at the period of the monthly illness. In some cases it is scarcely perceived at the periods, but returns in the middle of the interval between the periods. The pain is increased by standing, walking, and by sexual intercourse. It sometimes shoots down the thigh. The monthly illness is of an unusual kind, excessive or scanty or very painful. Various nervous pains are experienced throughout the body, and a highly nervous and hysterical condition may result from the chronic form of the disease.

In some cases the pain is neuralgic in character, and the term neuralgia of the ovaries has consequently arisen.

The **treatment** depends on the cause of the affection. It can only be said here that anything likely to excite congestion of the organs in the lower part of the belly is to be avoided. Constant standing, much use of the treadle sewing-machine, of the harmonium, &c., ought to be avoided. Good food, fresh air, sea-air, and sea-bathing are valuable. Hot water injections as advised on p. 502 may be tried. The evils of the use of laudanum or other preparation of opium, and of alcohol are very great, and the inducements to their employment many. They must be strenuously avoided.

Tumours of the Ovary (*Dropsy of the Ovary*).—While there is a variety of solid tumours of the ovary, the common tumour is one containing fluid. It is a cyst or sac, of every variety of size, some weighing as much as 30, 50, or upwards of 100 pounds. Its contents may be a watery, clear, straw-coloured fluid, or a fluid more gluey and tenacious and of varying colour. While the tumour may grow slowly, it has been stated roughly that the average duration of life after its beginning is under three years. These tumours are most common between the ages of twenty and forty years.

Symptoms.—In the early stages there may be practically no symptom, and the first indication may be the enlargement of the abdomen. The enlargement may be mistaken for pregnancy, though it is usually more or less rapid than that of pregnancy; and this mistake is more apt to be made if the monthly illness ceases or becomes scanty and irregular. As the tumour grows the patient becomes thin and exhausted, and disorders of the bowels arise increasing the exhaustion.

Treatment.—There is only one form of treatment of any value, namely removal of the tumour by surgical operation. It is an operation now attended by very great success when skilfully performed, and when undertaken in time before the patient's powers are exhausted. Withdrawing a quantity of the fluid by tapping is not now so common a method of treatment as formerly. It affords only a temporary relief,

the sac filling up again in a short time, and if frequently performed it may be a serious hindrance to the operation for removal, by causing adhesions between the walls of the sac and those of the belly cavity.

DISORDERS OF THE MONTHLY ILLNESS (*Menstruation*).

Absence of the monthly illness (*Amenorrhœa*).—Strictly speaking, the term amenorrhœa, meaning want of the monthly discharge, is only applied to those cases where the monthly illness has never appeared at any time. It is, however, also applied to cases in which the monthly illness has been present, but has after a time disappeared. This latter condition is more correctly termed **suppression of menstruation.**

It is necessary to notice this distinction, for, if a girl has reached the age when the illness might be expected, and it has not appeared, it is sometimes necessary to assure one's self that the non-appearance is not due to some obstacle to the escape of the discharge externally, the illness actually occurring, but the discharge being retained.

Absence of the illness through retention.—In the virgin condition there is a membrane, called the **hymen**, which stretches across the lower end of the genital passage. The membrane is as a rule not complete, a small opening existing in the centre, through which discharges from the womb escape. But in some cases, not frequent, the membrane is complete, and thus no discharge can escape. The obstruction may exist at the mouth of the womb itself. In such cases the symptoms of the monthly illness appear without discharge. At regular intervals pains in the back and sides occur, and with each return they increase in severity. The patient has a feeling of weight, and grows pale and sallow. The retained discharge, accumulating from month to month, causes the belly to enlarge and a tumour to appear, which undergoes regular monthly increase. The girl's friends putting the absence of discharge and the enlargement of the abdomen together suspect pregnancy, and many an innocent girl has thus come under unmerited rebuke.

It is even possible for such an obstruction to occur in some part of the womb or passage after the illness had become established, and this must always be borne in mind.

This condition is remedied by surgical interference, opening a way for the retained discharge to escape. Such cases are, however, always attended with risk.

Complete absence of monthly illness may also be due to some arrest of development of the genital organs. There are thus cases in which the ovaries or womb have been absent, or present in an undeveloped condition. In absence of the ovaries the girl does not exhibit the changes in form from girlhood to womanhood. The breasts remain small and the hips narrow, the voice is manly and harsh, and the appearance becomes masculine.

Absence of the illness through suppression, that is after the illness had become more or less regular, may arise from a variety of causes. It may depend upon a condition of general health or a poor quality of blood (see ANÆMIA, p. 234). The feeble condition of general health is often the result of over-work, over-pressure at school, improper quantity or quality of food, want of fresh air, confinement in the bad atmosphere of a crowded work-room, or of some acute disease, &c. The opposite condition of too full-bloodedness may also produce suppression of the illness. Disease is another cause, and especially consumptive disease of the lungs, disease of the kidneys, and digestive and nervous disorders. Emotion, fright or grief sometimes occasion the disturbance. The illness may be suddenly arrested by cold.

The absence from failure of general health is sufficiently evidenced by the paleness of the patient. She is wanting in energy, listless and languid. These cases are readily enough separated from those due to cold or full-bloodedness.

The **treatment** is regulated by the cause. It is sufficient to state the kind of treatment needful in the variety dependent on the general health, and that due to sudden suppression owing to cold, &c. It includes good nourishing food of a plain kind, containing a fair proportion of animal food, sweet milk, eggs, fish, fowl, beef, soups, &c. The bowels must be kept regular, a saline medicine, such as seidlitz, Hunyadi Janos mineral water, or the effervescing citrated magnesia being given, if required. Especially is it necessary to insist upon abundance of life in the open air, and moderate exercise. While overwork is extremely hurtful, the absence of some bodily or mental occupation is also injurious. Change of air and sea-bathing are strongly advised, and, to those who can afford it, a visit to some of the Continental spas is recommended, especially Kissingen, in Bavaria, Kreuznach, in Rhenish Prussia, Schwalbach, in Nassau,

Spa, in Belgium, Bourboule, in France. In England Woodhall Spa, in Lincolnshire, is recommended. Much standing, stooping, or prolonged sitting, is to be avoided. As to medicines it is impossible to state what suits every case, but tonics belong to the kind required. Iron and arsenic are particularly valuable.

The following prescription may be employed:—

Reduced Iron,	grains	36
Arseniate of Iron,	,,	1½
Extract of Nux Vomica,	,,	9
Sulphate of Quinine,	,,	12
Extract of Gentian,	,,	24

Mix and divide into 18 pills.

A half gradually increased to one pill is to be taken thrice daily after food.

These pills must always be taken after food, never on an empty stomach.

Further the full dose is not to be taken all at once. To begin with, let a few of the pills be divided into two, and let a half be taken after meals thrice a day for two or three days, then let a half be taken after two meals and a whole one after the principal meal, and so let the dose be increased till at the end of a week three pills daily are being taken.

It is important also to notice that the use of the pills must not be stopped suddenly but gradually, a half pill less being taken for a couple of days, then another half less, and so on till in a week their use is stopped altogether.

Arsenic is apt to disagree with some stomachs. In such cases it may be altogether left out of the pills.

While these directions have been given, it is desirable to say that no unskilled person should attempt to treat such a disorder if skilled advice is obtainable.

Sudden suppression, as may arise from cold, usually happens in full-blooded people, and is accompanied by severe pain in the back, quick pulse, feverishness, flushed face, headache, &c. Let the patient's feet and legs be placed in a hot mustard bath for half an hour. She should be then put into a warm bed with warm foot-pan, and should have frequent mild warm drinks, following a large dose of opening medicine, castor oil for example. If this is not sufficient, and the case seems urgent, fever being high, place hot mustard poultices over the lower part of the belly, and give 5 to 10 grains of Dover's powder according to age.

Irregularity or Scantiness of the Monthly Discharge, in which the discharge occurs after more than usually long intervals, or at irregular intervals, or in which it occurs regularly but in small quantity, is commonly dependent upon conditions of the general health similar to those producing absence of discharge, and is to be treated on similar lines.

Excessive Monthly Illness (*Menorrhagia and Metrorrhagia*).—The monthly illness may be excessive, because occurring too frequently. Such conditions indicate a depressed condition of general health, and are also associated with disordered states of the womb. They are not uncommon at the period of change of life. The tonic treatment recommended for absence of the illness is likely to prove beneficial.

There are, however, two special forms of excess. One of these is called simply profuse menstruation, what is meant being that the discharge is too free or lasts for too long a time, returning at the regular periods perhaps. The proper term for this is **menorrhagia.** The other form is not strictly discharge at the monthly periods, but a loss of blood occurring at other than the monthly period, at least a discharge of blood from the womb, occurring independently of the monthly period. This is called **metrorrhagia.**

The first form, that of excessive loss at the period, occurs under various circumstances. It must be observed, however, that there is no absolute quantity of discharge to be regarded as the healthy standard (see p. 482). Each woman knows what, under ordinary circumstances, she is accustomed to, and that is her standard. The excessive loss may depend upon bad conditions of health, arising from Bright's disease of the kidney, scurvy, consumption, &c. Commonly it is a symptom of chronic disease of the womb. It is sometimes the only symptom of fibroid tumour of the womb (p. 503). In cancer of the womb, polypus, displacement, congestion, and in many other alterations in structure, it is present.

The excessive loss produces a blanched appearance of the patient, and according to the degree of excess is more or less exhausting. The second form is met with under similar conditions, and the first often leads up to and merges into it.

The **treatment** of both forms is practically identical. The patient should rest in bed as much as possible during the period, undertaking no exertion. If the loss of blood is great and threatening, whether during the period or not, she must lie in bed perfectly quiet and lying on

her back. Mild but nourishing diet in small quantities should be given often—milk, light soups, &c. The very valuable and most readily obtainable drug is ergot or spurred rye, in the form of the liquid extract. A half to one teaspoonful is given in water or syrup every third hour as long as necessary. Another useful drug is the tincture of witch-hazel (*Hamamelis virginica*, p. 835), in doses of five drops in water every third or fourth hour. A medical man would, in urgent cases, plug the passage by inserting pledgets of soft cloth, sponge, silk handkerchiefs, &c. In the intervals good nourishing food, bracing air, moderate exercise, &c., are valuable, as well as the iron tonic advised for absence of the discharge on the preceding page.

In certain cases of persistently recurring attacks, due to tumours, and threatening life, a surgeon might recommend removal of the ovaries, or other operative interference.

Painful Monthly Illness (*Dysmenorrhœa*).—Painful menstruation is exceedingly common, and many women who suffer severely at each period seek no advice nor relief, because they believe a certain amount of pain is a natural accompaniment of the illness. This is not so. Any actual pain is a departure from the proper state of affairs, and ought not to be endured, if it can be got rid of.

The **causes** of the pain are numerous, just as the cause of every other menstrual trouble may depend on a variety of circumstances. In one set of cases the cause is a mechanical one, and consists in some obstacle to the easy flow of the discharge, undue expulsive efforts of the womb being thereby occasioned. Thus the canal leading from the womb may be very small or contracted, the womb may be displaced and bent, so that the canal is encroached on, or at one point blocked by the bending, clots may form readily, and stop the way or require specially violent efforts to expel them, or the way may be barred by a tumour. All these instances come under this class of cases as mechanical causes of painful menstruation. Another set of classes often occurs in which the pain is of a congestive or inflammatory sort, and in others shreds of membrane and casts of the womb are expelled. In a fourth set the pain is more neuralgic in character, not seeming to depend on any special condition of the womb, while the pain in some cases arises from the ovaries.

The commonest cause of painful menstruation is some mechanical obstruction to the flow of the discharge, due either to narrowing of some part of the canal of the womb, or to some displacement. The occurrence of any clots or shreds of membrane will certainly increase the pain by the difficulty of their passage along the narrowed canal.

The **symptoms** of this variety are very intense pain, sometimes agonizing, leading in some cases to fainting, hysterical attacks, or even delirium. The pain often begins before the discharge, and is relieved when any quantity passes, as it sometimes does, in gushes. It begins deep in the belly, but radiates to the groin, thighs, and back. Headache and vomiting are common, and there is often tenderness over the womb and ovaries. The pain may persist throughout the illness. Moreover, the obstacle to the flow tends to produce a congested condition of the womb.

The cases dependent upon congestion have similar symptoms.

Those accompanied by discharge of shreds of the membrane are recognized by the presence of the membranous fragments, and the pain is most intense just before the passage of the membrane, after which it is relieved. When the pain is more ovarian than belonging to the womb, it usually begins a few days or a week before the discharge appears, and may cease with its appearance. It is felt in the situation of the ovaries, in the groin, and commonly on the left side, and there is tenderness over this position. Vomiting and hysterical attacks are common in it. Probably there are few cases really neuralgic in character, those classed thus being likely due to some obscure condition of the ovaries.

Treatment.—The general treatment of painful menstruation consists in rest in bed during the attack, and the employment of hot applications, hot-water bottles, hot fomentations, &c. Great relief will be experienced, in many cases, by the patient taking a hot bath, lasting for twenty to thirty minutes, before going to bed, on one or two nights before the illness is expected. The pain will be relieved by some preparation of opium or other similar soothing drug. The following pill is good for that purpose :—

Morphia, ...	$\frac{1}{12}$th	grain.
Extract of Indian Hemp, ...	$\frac{1}{3}$d	„
Extract of Hyoscyamus,................	$\frac{1}{2}$	„
Extract of Gentian, ...	1	„

Make into one pill.

Two or three of these may be taken at intervals of two or three hours between each pill.

Instead of this a dose of 25 to 30 drops of

laudanum, with 5 drops of tincture of belladonna, may be used.

While such a remedy is often necessary, the danger attending the use of any preparation of opium must be strongly pointed out. The desire for the drug becomes strong, and it is used more frequently in ever-increasing quantities. Many women contract a fatal opium habit from using it at such periods. In such a time of suffering, also, stimulants are sought, and relief is obtained from them. The craving for them grows just like the craving for morphia. Thus too many women have become the slaves to opium or whisky, which was originally taken for the relief of urgent suffering.

Under such circumstances it cannot be too strongly urged that everyone suffering in this way should not attempt to treat herself, but should seek competent advice. It is probable that a skilled medical man would discover some unusual condition, which was the cause of the pain, and which he might be able to rectify without the use of drugs, that might in the end prove more disastrous than the original ailment. Thus a displaced womb could be restored to its proper position, and perhaps the painful menstruation could be cured, a contracted passage could be widened, and other unhealthy conditions might be got rid of.

During the interval between two illnesses much relief may be obtained by attention to general conditions of health. Good plain food should be the rule; a daily movement of the bowels ought to be obtained by mild opening medicine, if necessary—for example, a wine-glassful of Hunyadi Janos mineral water each morning on an empty stomach. Opening pills should be avoided. The patient should be warmly clad, with flannel next the skin, and it is necessary to avoid all undue tightness of dress. Fresh air, moderate exercise, avoidance of fatigue, are all of the utmost consequence. Any gouty, rheumatic, or weakly condition of health, such as anæmia (p. 234), needs to be treated. If the pain is felt over the ovaries, 20 grains bromide of potassium, dissolved in water, may be tried every three or four hours.

AFFECTIONS OF THE BLADDER, &c., IN WOMEN.

Painful, difficult, or frequent passing of water very often occurs in women as a consequence of some affection of the womb or genital passage. Inflammation of the passage (p. 498) is apt to spread up to the canal leading to the bladder, and cause frequent desire to pass water, an act which is likely, under these circumstances, to be attended by a hot smarting or burning pain. The same condition may cause spasm at the neck of the bladder, and lead to inability to pass the urine. Specially likely is it that an irritating discharge will set up such a condition and lead to much pain and discomfort, a result that constant care and cleanliness would do much to avoid. A displaced womb, by pressure on the bladder, will readily set up an irritable condition, manifested by pain and a frequent desire to pass water, or will block more or less the passage from the bladder and occasion difficulty of micturition, as the act of passing water is called. Tumours connected with the generative organs may have similar effects. Besides the prominent symptoms of frequent or painful or difficult micturition, there is often produced considerable difficulty in walking, and in turn the walking aggravates the other symptoms. Painful and difficult or frequent micturition may also be quite independent of any disorder of womb or genital passage, and may be occasioned by some unnatural state of the urine, undue acidity, or otherwise altered characters, the result of disease of the kidney or bladder or some constitutional state.

Treatment.—Rest and the use of hot applications give very speedy relief. Heat may be applied in the form of hot-water injections, hot cloths, or hot bottles close up to the parts, or the patient may sit down in a hot bath. Medicated pessaries are also of great value. These are made of cacao butter, in the shape of miniature sugar loaves, some soothing drug being mixed with the cacao butter. The best are those made with extract of belladonna. Each pessary should contain 3 to 5 grains of this extract. The pessary is pushed well into the genital passage, a diaper is then put on, and the patient should rest for some time. This may be employed after the hot-water injection, bath, or fomentation. But the patient must bear in mind, that, though such treatment relieves for the time, it is necessary, if the cure is to be permanent, for any cause of the disturbance, that may be present, to be found and removed.

DISEASES OF PREGNANCY.

Derangements of the Stomach and Digestion are exceedingly common in pregnancy, are in fact almost constant, and are to be regarded as quite natural, if within certain

limits. They depend mainly upon the sympathetic nervous relationship existing between the womb and digestive system; to some extent they are due to the pressure of the enlarging womb, and in some cases may be very marked because of displacement caused by the increased weight of the organ. They may occur throughout the whole course of the pregnancy, but they are often worse in the early months, beginning within a few weeks of conception, and being markedly relieved about the period of quickening, when the womb rises up into the belly. Perhaps the relief at this time is due to the greater room for growth thus afforded, and the consequently lessened pressure. Some women, however, scarcely suffer at all from such disturbances, while in others the distress is excessive. It also, sometimes, happens that a woman who has been much disturbed for two or three pregnancies passes through another almost without them, and the reverse also often happens.

Vomiting is one of the commonest of these disorders, and because of this is counted as one of the earliest and most usual signs of pregnancy (see p. 487). It is only when excessive that it should receive treatment, and it often happens that nothing gives relief. The patient should begin by maintaining the regularity of the bowels, which is best done by a wine-glassful of Hunyadi Janos mineral water, taken each morning before rising. This affords much relief if regularly taken. The effervescing citrate of magnesia is also useful. Then careful attention should be paid to the diet, as the vomiting may be largely controlled by finding the food that agrees best. Marked relief is frequently obtained by taking a cup of warm tea before rising, or by breakfasting in bed, and not rising for some little time afterwards. If such means fail, let the patient try the effect of taking small quantities of food often, and among the kinds of food milk, and milk with soda, are to be preferred, or milk and lime-water. Used in this way barley-water is highly spoken of. Frequent sips of iced milk may be found to allay the irritability. Stimulants may seem desirable, such as brandy in soda-water, or brandy or whisky in milk. The only medicine to be recommended as a soothing agent is bismuth, which may be taken several times a-day in 10-grain doses in water, or 1-grain doses of oxalate of cerium may be tried. A pessary of belladonna (see PESSARIES) has now and again succeeded when other means failed.

In some cases, happily very rare, the vomiting defies treatment, and is so persistent, with even the smallest quantities of food, that the patient becomes much exhausted, and brought into a condition of great danger. It is under such circumstances that a medical man would consider whether he were justified in inducing premature labour. This is a question for a skilled physician carefully to consider; it is here only mentioned as a last resort when the life of the mother seems threatened.

Acidity, Heartburn, and Painful Digestion are other forms of disturbance, and sometimes are the only forms, vomiting being entirely or nearly entirely absent. Bismuth in 10-grain doses, or half a tea-spoonful of the ordinary bicarbonate of soda (baking soda), or bicarbonate of potash, dissolved in water, is useful for these disorders, though the relief is only temporary. To the soda, dissolved in water, a tea-spoonful of sal-volatile (aromatic spirits of ammonia) may with advantage be added.

Constipation is best met by the use of the Hunyadi Janos mineral water, as recommended for vomiting.

Looseness of Bowels may occur every now and again. It should be met if possible by change of diet, the use of lime-water and milk, &c. If these means fail, 5 to 10 drops of laudanum in water may be employed, but this is to be had recourse to sparingly and with care.

Perverted Appetite or **Loss of Appetite** is another of the troubles of pregnancy. The craving for improper articles must be resisted, but a feeble appetite must be coaxed, and careful dieting will usually be sufficient to meet it.

Disturbances of Breathing are happily not so common as those of digestion. The mere bulk of the enlarging womb will occasion some difficulty of breathing. To meet this the patient must dress in the most suitable way. Difficulty of breathing is occasionally due to asthmatical attacks or bronchitis, and where such exists it would be well to obtain competent advice without delay. (Refer to pages 270 and 273, where these affections are discussed.) Cough ought not to be neglected. In some cases its violence threatens to provoke a miscarriage.

Disturbances due to pressure are frequent in the course of the child-carrying period, and specially, as might be expected, towards the end of the period. The **bladder** is peculiarly apt to be pressed upon, and frequent passing of water, pain in the act, or difficulty in emptying the bladder may be experienced. Dribbling of urine may arise from pressure on the neck of

the bladder interfering with its proper emptying, and may be thus the result not of inability to retain the water, but from the bladder being constantly overfull. A bandage carefully adjusted while the patient is lying down will often relieve such symptoms by the support it affords to the womb. Occasionally the use of a belladonna pessary (see PESSARIES) or the application of hot-water pads relieves irritability. Sometimes the patient will overcome difficulty in making water by changing the position usual in the act of passing water, but sometimes it is necessary to pass the catheter to empty the bladder.

Dropsy, Varicose Veins, and **Piles** are frequent in pregnancy as the result of pressure by the enlarging womb on veins preventing the due return of blood. The feet and legs suffer from the dropsical swelling, and the veins of the inner side of the knee and also of the ankle become swollen and prominent, forming varicose veins (see p. 247). Sometimes the ankle becomes much discoloured, in consequence, as if it had been severely bruised. For these conditions there is no cure. They will in nearly every instance disappear after delivery. Some relief may, however, be given by supporting the womb with a bandage put on as the woman lies on her back, and by supporting the veins of the leg with properly-adjusted bandages. All garters should be discarded and nothing worn tight round the knee. Elastic stockings, if properly fitted, are very useful. The bowels should be regulated with the Hunyadi mineral water already recommended. Piles often also disappear after delivery. Certainly no operation for their cure should be undertaken during pregnancy. If they are painful, bathing with very hot water gives great relief, and the gall and opium ointment or the tincture of witch-hazel (the American Pond's Extract) may be applied to relieve pain and arrest bleeding. In this case regularity of the bowels is everything.

Dropsy during pregnancy may, however, be the result of an affection of the kidney, termed **albuminuria** (see p. 302). In such a case it affects not the lower limbs merely but the whole body, and is a much graver condition than the dropsy due to mechanical pressure. The legs are greatly swollen, and the face puffy. There are also other symptoms, such as headache, dimness of sight, and in severe cases convulsions. The symptoms may, however, not be so serious, and after delivery they may entirely disappear. But a patient who, during pregnancy, suffers from swelling not of the legs only but also of other parts of the body should seek competent advice at once. It is not a condition for which treatment can be definitely laid down here.

Another form of dropsy, called **dropsy of the amnion**, may be mentioned here. It has been pointed out (p. 485) that the growing child is inclosed within a double sac between the walls of which fluid is contained, the waters. In ordinary circumstances the quantity of fluid would not be more than 2 or 3 pints, but in some cases the quantity is enormously increased. It produces in such cases most excessive enlargement, and is a source of extreme discomfort to the mother, interfering with movement, affecting breathing, &c. It is usually after the middle of pregnancy that the excess shows itself, not much before the fifth month, and it is commoner in twin pregnancies. When the distension is very great the breathing may be so difficult that some treatment is needed. Nature has often afforded relief by the membranes spontaneously rupturing, inducing premature labour. If it were proved necessary, a physician would imitate this procedure. It is not a condition, however, threatening the mother, but it does seriously that of the child.

Nervous Affections are not uncommon during the child-bearing period. It is quite common for pregnant women to manifest marked alterations in character, an unusual irritability of temper, a tendency to fretfulness, capriciousness, or melancholy, hysterical tendencies also, the woman being easily moved to tears or laughter. Indications of nervous disturbances are also found in perversions of taste, smell, &c. More than this, however, there may be marked signs of mental disturbance, and actual insanity. Convulsions sometimes occur, which may be associated, as mentioned above, with the altered condition of the urine, called albuminuria. As these affections are more common during and after delivery they will be considered later (see p. 517).

Miscarriage and Abortion are both used to indicate that the offspring has been expelled from the womb before the full period of pregnancy is completed. Abortion is the word which ought to be employed when the expulsion takes place before the eighth month, before the period, that is, when the child has the chance of surviving, and miscarriage is employed after that period, when it is still possible for the child to live. The phrase **premature labour** is still

better to indicate the latter state of affairs. There is no doubt that the product of conception is very often expelled from the womb within a few weeks of conception taking place without the woman being aware of the fact. She thinks her monthly illness has only been delayed. The commonest period for abortion is between the eighth and twelfth week of pregnancy.

The **causes** are very numerous. Accidents, blows, falls, &c., indiscreet exertion in dancing, for example, irritation arising in the bowel from the presence of worms, or the occurrence of diarrhœa, irritation in the genital passage or womb itself, all these may cause it. It may be due also to disease, diseases attended by fever, or any serious disease whatever; it may be the result of a diseased ovum, of tumours connected with the womb, or displacements of the womb. Strong emotion may excite it, and various drugs act on the womb in a way to excite it to expel its contents.

It must be noted also that the womb may readily acquire a habit of expelling its contents at a particular period. If abortion has occurred once or twice about the same time, there will be special danger of the same occurrence about the same time in future pregnancies.

Symptoms.—The chief symptom, to begin with, is pain—pain in the back and in front also. If the abortion is very early, the pain may be trifling, but the more advanced the pregnancy, the larger will be the mass to be expelled, and the greater the pain. Previous to the pain, a cold uneasy feeling is experienced at the lower part of the belly in front, along with a sense of weight, and the morning sickness and fulness of the breasts may have disappeared. The pain lasts for a time, passes off, and after a longer or shorter interval, returns. A discharge of blood also appears, which varies in amount in different cases. On the quantity of blood which has been discharged one bases an opinion as to whether or not the threatened abortion can be prevented. If the discharge has been considerable, and repeated, and if the pains keep returning, there is little hope of averting the expulsion of the contents of the uterus. If the pregnancy is advanced to the formation of membranes and fluid, and if the membranes have ruptured and the waters escaped, that is conclusive evidence that the process cannot now be checked.

If any reliable information could be obtained as to whether the offspring were alive or not, that would be a great aid in solving the chief difficulty of the situation. If its death were certain, the expulsive efforts of the womb would be encouraged; if its life were certain, they would be restrained if possible. The feeling of coldness and weight referred to are held as indicating the death of the offspring. Should the pregnancy be advanced beyond the period of quickening the cessation of all movements on the part of the child would lead to the conclusion that it was dead. This must not be too readily accepted as proof. It has often happened that the movements have ceased for days, till the mother became convinced of the child's death, and yet it has been born alive. In some cases the expulsion of a dead ovum has not taken place for a long time after the death had occurred.

When the abortion or miscarriage actually occurs, the important thing to secure is that everything is expelled from the womb. It is always desirable, in order to make certain that this has occurred, for all clots, &c., to be kept till seen by the medical attendant. In abortion in the earliest months everything is usually expelled together in the form of a fleshy mass, but from the third month there is greater liability of something being retained, which will lead to subsequent trouble. After the sixth month the miscarriage becomes similar to labour at full time, but more easily accomplished.

Treatment.—The first and most essential part of treatment is rest, complete rest in bed, the patient lying flat, with head low. If the abortion or miscarriage is only threatened this is the first and chief means to ward it off. Unstimulating light diet is to be given, and always cold. If pain is the chief symptom, an opiate is very valuable, say 30 drops of laudanum, which would be best given mixed with a teacupful of thickish starch as an injection into the bowel. If a discharge of blood is the chief symptom acid drinks and a lead and opium pill is advised. Repeated doses of opiates should, however, never be given without medical orders. If the abortion is arrested, rest must be continued for a prolonged period, and great care exercised. If such treatment does not arrest the expulsive action, if the pains are returning at regular intervals in strength, and the discharge of blood is considerable, and certainly if the waters have come away, other treatment, designed to aid the process, is needed. For this purpose from a half to a tea-spoonful of liquid extract of ergot is given every third hour till everything is expelled.

A woman who has miscarried or aborted

must be treated in every way as one who has been delivered at the full time, and must be allowed as long a period of rest in bed afterwards. Further, such an one must remember that she runs special risks of repeating the same performance at a similar period of a later pregnancy, and must, therefore, take special precautions about such a time, avoiding undue exertion and fatigue, and, it is specially to be noticed, *avoiding all sexual excitement.*

Flooding is the ordinary term applied to profuse loss of blood from the womb. It may occur either before the period of confinement or afterwards. Of course loss of blood occurs in abortion, but it is attended usually by the pains, which indicate what is going on. Alarming losses of blood occur within the last three months of pregnancy, due to the placenta, or after-birth, occupying a peculiar position in the womb. This is called properly **placenta previa.** The after-birth is situated partially or wholly over the passage, through which during delivery the child must pass, and, therefore, it is separated either wholly or partially some time before the birth can occur. By this separation blood-vessels are opened, and the womb not being able, owing to its contents, to contract and close the bleeding vessels, a great loss of blood occurs very speedily. The actual determination of this condition can only be made by a medical man after a careful examination; but a profuse loss of blood occurring within the last three months of pregnancy, without any apparent cause, should cause a woman to seek immediate skilled advice. Sometimes there is no sign of this condition till the full time, after labour has set in, and then the loss of blood may be immediately so great that the life of the mother is threatened before any assistance can be obtained.

Treatment.—Medical aid cannot be dispensed with. All that others can do is to put the patient to rest on a hard bed, with low head, and to give low diet, cold, all stimulants being avoided. If the loss of blood is great and danger threatening before aid can arrive, attempts may be made to stop the flow of blood by plugging the passage. This is to be done by pushing up strips of lint one after another, or pieces of a silk handkerchief, till the whole passage is thoroughly packed. Tea-spoonful doses of the liquid extract of ergot may also be given in cold water every third hour.

Flooding after delivery will readily occur if the after-birth has not been expelled. It also occurs when everything has gone on satisfactorily, the after-birth has been removed, and all has seemed well, owing to the womb relaxing, because of want of vigour, and permitting the torn vessels again to open and pour out blood. The **symptoms** are not only the visible flow of blood, but the patient complains of faintness or dim sight; she is white and cold, with clammy skin. In the former case the after-birth must be got rid of. A medical man would probably pass up his hand into the womb and remove it. In the absence of such assistance let a large dose of the liquid extract of ergot be given, one to two tea-spoonfuls. Let someone place the *cold* hand over the lower part of the woman's belly and rub, with the design of exciting the womb to contract. Cold water may be dashed over the belly and cold water injected into the genital passage by an enema syringe. Similar treatment is to be adopted if the bleeding occurs after the after-birth has been removed.

Molar Pregnancy or Blighted Ovum.—Sometimes the product of conception dies without abortion speedily occurring. Owing to some part of it remaining connected with the womb, growth goes on, the membranes undergoing thickening and degeneration. This may continue till at length a fleshy mass is discharged called the **flesh-mole.** In other cases one of the membranes undergoes a peculiar development, so that a mass is produced resembling a bunch of currants, when seen floating in water coloured with some of the discharged blood, like a mass of "white currants in red currant juice." This is the **vesicular mole.**

Symptoms.—In each case the woman usually suspects something is wrong. The usual symptoms of pregnancy are experienced for a time, but the enlargement of the belly is much more rapid than usual. In the case of the fleshy mole, the growth is so rapid that at the end of the third month the enlargement is as great as is customary at the end of the fifth. In the case of the vesicular mole the normal symptoms go on till about the third month, and then enlargement becomes very rapid, and is more towards the side than upwards. The other usual symptoms are indistinct, the patient feels differently from what she did in other pregnancies. Watery discharges, mixed with blood, may occur, and the feelings of movement of the child are not experienced.

The mole is usually expelled after six months. It has sometimes occurred in twin pregnancy

that one of the ova has undergone such degeneration, and the other has followed a normal development, so that at the sixth month a living child has occupied the womb along with a vesicular mole. In such a case the danger is that the expulsive efforts of the womb do not end with ridding it of the mole, but go on to the expulsion of the fœtus, at a time when it cannot survive. Some cases are recorded, however, in which the mole was expelled, and a healthy living child was born at the full time.

Treatment of such cases rests, of course, with a physician. In any case where such cannot be obtained soon, and there is considerable watery and bloody discharge, especially if some of the currant-like material has been expelled and shows clearly the nature of the case, error can hardly be committed by giving full doses (teaspoonful) of the liquid extract of ergot of rye, every two or three hours, as long as seems necessary.

DISEASES AFTER CHILD-BIRTH.

Flooding (*Hæmorrhage*) has already been sufficiently discussed in the previous paragraphs (p. 515).

Milk Fever.—On the third day after delivery the rush of milk to the breasts becomes usually very marked, and is frequently attended by considerable disturbance, feverishness, quick pulse, and headache. The breasts are very full and may be hard, and markedly knotted and painful. This is the condition called **milk fever**, and also called popularly a **weed.** If care has been exercised all through the period of delivery and after it, and everything has been scrupulously clean, if also the directions given on p. 496 have been followed, and in particular if the child has been regularly put to the breast every third hour (see p. 438), the chances of such a condition arising are extremely small.

Treatment.—Give a strong dose of opening medicine, a double-strong seidlitz-powder being preferred, or a full ounce of castor-oil. Put the child regularly to the breast every 2½ hours. If, owing to the swelling of the breast, the nipple is below the level of the breast, let it be pulled out by means of a breast-exhauster; and if the child cannot empty the breast, let the breast-exhauster be used as well. It is necessary to keep down the swelling in every way possible. Much relief will be given by laying over the breasts a soft handkerchief, soaked with ice-cold water. This may be renewed every quarter of an hour or so, if it is giving relief, but care must be taken not to overdo this, and not to permit the mother's clothing to become wet in the process. Warm applications, in some cases, are advised, but are to be used at first with caution. The cooling application should first be tried. If the breasts are knotted, gentle light rubbing with oil aids their relief. Meantime liquids must be given to the mother sparingly, and more solid food given. She may suck a small piece of ice to relieve thirst.

If, within a very few hours, these measures have not given relief, 10 grains of Dover's powder may be given in water, *but not until the bowels have been freely opened.* A second may be given in four hours, and, if it seems useful, a third six hours after the second, but no more without advice. The bowels will probably require to be opened again by medicine, as the powders have a binding effect.

Affections of the Breast after child-birth are very commonly due to the constant worry and irritation of cracks and fissures of the nipples. These are to be avoided by regular nursing, by carefully bathing the nipples after each nursing with cold water and drying them, and by the use of some agent which will toughen the skin, of which the best is glycerine of tannin, or glycerine of borax. It is not a matter of wonder if a mother suffers from tender nipples who permits her child to be continually at the breast, so that one nipple or another is constantly in the child's mouth. Some mothers suffer from such an excessive flow of milk that the dress is continually wet and the breast continually in a milk-bath. This will naturally make the skin tender and readily crack. Keeping the breasts as dry as possible, and limiting the flow of milk, if possible, by dieting, are the remedies. If the nipples are hacked and painful, the use of a nipple shield (see Plate VIII.) during nursing gives much relief, the other treatment already indicated being employed.

It is needful to bathe off, with cold water, the tannin and glycerine or other application before putting the child to the breast.

Abscess or **"Gathered Breast"** often results from neglected cracks and painful nipples. The breast becomes full and swollen and painful, especially over one part, which also becomes hard. The breast should be treated as recommended under milk-fever, first with the iced-water, and then, if it fails, with hot water

applications. A brisk dose of opening medicine (seidlitz-powder) should be given. If matter forms, it must be "let out" by the abscess being opened, and should on no account be allowed to burst.

Whenever the breasts are large and swollen, great relief is given by a bandage passing under the affected breast and over the opposite shoulder, so as to support it.

It is also necessary to keep down the swelling of the breasts as much as possible by regular removals of the milk. If this is not properly done by the child, a breast-exhauster, or breast-pump, must be secured at once, and the milk must be frequently drawn off by its means. The exhauster and its mode of application are shown in Plate VIII. It is advisable to apply the exhauster every two hours or so, to remove by its means small quantities of milk frequently rather than to attempt to remove a large quantity at one time. If this is done and the other measures advised are adopted, threatened inflammation of the breasts will often be speedily subdued.

Convulsions occurring during pregnancy or labour, or after child-birth, are of very serious meaning. They are commonly due to the condition known as albuminuria (see pp. 295 and 513), although they may occur without such a condition, caused, as some believe, by a too watery condition of the blood inducing a state of bloodlessness (ANÆMIA, p. 234) of the nerve centres.

Symptoms.—Convulsions may occur without any warning, but usually warning of the coming attack is given by the occurrence of headache, usually of the front of the head, of a very intense kind, and likely to be continuous when the fit is near at hand. Another warning sign is derangement of vision, dimness or cloudiness of sight, or some other disturbance of clearness of sight. In a few cases severe pain is felt over the pit of the stomach. One sign which ought not to be disregarded is puffiness of the face, and swelling of the ankles, feet, and external genital organs. Such a condition ought to lead to immediate medical advice. The fit itself is of a marked kind. The eyes are fixed, within a few seconds the face and eyelids are spasmodically twitched, the eyeballs roll, and the face is pulled down first to one shoulder and then to the other, the mouth being also twisted, and the upturned eyes show only the white part of the ball. The convulsive movement then passes quickly over the rest of the body, and for a little the whole body is stiff, head being bent back, limbs stretched out, and hands clenched. After a brief period irregular spasmodic movements occur of great violence. The face is violently twitched, the arms jerked, the tongue is often caught between the teeth and severely bitten, and froth mixed with blood from the tongue escapes from the mouth. Breathing is suspended till the face becomes purple. Motions from the bowels and water from the bladder are often passed. All this time there is complete loss of feeling and consciousness. As the fit passes off the spasms become less, the movements gradually cease, breathing becomes natural, and the face loses the purplish hue, and consciousness may be soon restored, or the patient may lie in a heavy torpor for some hours. When consciousness is restored the patient complains probably of headache and a dull stupid feeling. One attack may succeed another, consciousness not returning in the intervals, or there may be but one attack altogether.

The more severe and prolonged the attack, and the more frequent its recurrence, the graver is the case, though the author has seen one attack follow another for a couple of hours, and recovery take place. One in every three or four cases proves fatal.

If the convulsions occur before labour has set in they are extremely likely to provoke labour, and thus the life of the child is threatened. When labour is brought on it is often accomplished with great rapidity. The birth of the child has, however, a tendency to lessen the severity of the attack.

Treatment.—Very little can be done by an unskilled person. A medical man would probably administer chloroform, and if labour had begun would, if possible, effect delivery. Harm would not be done if, when medical aid was not obtainable, a draught containing 20 grains of chloral hydrate, dissolved in water and simple syrup, were given immediately after one attack to prevent, if possible, a second. The dose could be repeated in three or four hours.

Insanity may occur during the child-bearing period, during labour, or after delivery. It is most common in those with child for the first time, and in many there is an inherited tendency. In cases occurring during the child-carrying period, or after delivery, the commonest form is melancholia, evidenced by great depression of spirits and delusions, and when the case

is a severe one there is a tendency to suicide. These cases are more apt to occur in weakly, ill-nourished women, or those who have been much reduced by frequent pregnancies, prolonged nursing, or intemperance. Insanity during the progress of labour is frequently in the form of maniacal excitement, occurring during the most painful part of the process. The attack of mania may also occur some time after delivery, within a week or ten days, and occurs suddenly, or after a period of sleeplessness. There is considerable fever, small throbbing pulse, and bright eyes. The patient regards her attendants with suspicion. She talks excitedly, and the talk passes into raving, and she may attempt her own or her child's life. There is great sleeplessness, and the milk and discharge cease. Digestion is very seriously disturbed, the urine is high-coloured and scanty, and the bowels usually costive, though they may be loose. Recovery occurs in nearly three-fourths of the cases, that from mania may be within three or four weeks. Melancholia is less threatening to life but more to reason. It may last from a few weeks to a year or more, but most of the recoveries occur within six months.

Treatment.—Mania occurring during labour is met by chloroform. If it occurs afterwards the bowels should be unloaded by means of a simple injection of warm water and soap, and 20-grain doses of bromide of potassium in water may be given every four hours. But such cases are too serious and demand too much skill and care to be treated by any but qualified persons. The melancholic form needs, above all, careful dieting and quietness, freedom from worry and annoyance, kindly and watchful attendance, which had better be given by strangers than by the patient's own friends. A woman who thus suffers, or has suffered, should not attempt to nurse her child.

Puerperal Fever (*Child-bed Fever*).—This is one of the most appalling diseases that may follow child-birth. In most cases it is fatal within a very short period, ten days or so after delivery. It may be regarded as due to the passage into the blood of some poisonous material, probably of the nature of a living organism, such as has been discussed in Section XIII., which multiplies in the patient's body, and produces by its activity all the symptoms of the disease. The poisonous material may come (1) from the patient herself, or (2) may be introduced from without by, unhappily it is so, the doctor, the midwife, the nurse, or other attendant, or (3) as contagion from some other disease. Thus, to take examples, a patient may have had a miscarriage, the whole of the after-birth, membranes, &c., may not have come away. The retained portions may undergo changes of decomposition in the womb. Suppose now the woman again becomes pregnant. After delivery some of this decomposed material may pass into the blood and occasion the fever. Or a similar thing may occur at an ordinary confinement, fragments of the after-birth may remain behind, undergo putrefaction, and occasion the disease. Thus the woman may infect herself. A medical man may convey the disease by attending a confinement after assisting at a *post-mortem*, or after dressing foul wounds, &c. Similarly it may be occasioned by the use of unclean instruments, sponges, syringes, &c. An example of the third means of communication is afforded by erysipelas and scarlet fever. These diseases attacking a woman recently confined assume extremely violent and fatal characters, due to the peculiar condition in which necessarily the woman happens at that time to be.

Puerperal fever is a contagious disease. The danger of it being carried from one suffering from it to another patient in the process of confinement is enormous. No conscientious medical man will go from a case of puerperal fever to attend another confinement case without previously taking the greatest precautions against carrying the disease with him.

The disease, it will thus be understood, does not assume necessarily the same form in each case. In one apparently the poison is absorbed in a very fine form, and multiplying in the blood produces violent fever, diarrhœa, delirium, &c. In others it is absorbed, as it would seem, by the mouths of the open veins of the womb, in the form of larger particles, which, being carried with the blood current through the body, are arrested in various places, and form small abscesses. In such cases little abscesses may be visible on the skin, on the fingers, &c. In other cases the disease is in the form of an acute inflammation within the belly, as peritonitis (see p. 190), or as inflammation of the womb itself. Inflammation of the lungs and other organs may speedily arise in the course of the disease, due, doubtless, to the conveyance to these organs of some of the poisonous material.

Symptoms.—All of the various forms cannot be described, but we may state in some detail the characters of the fever in general. It begins

usually within three or four days after delivery, perhaps with a shivering fit (rigor), headache, and depression. The fever soon runs up to a considerable height, 103° or more by the thermometer (see p. 10). The pulse is rapid and feeble, the skin dry as well as hot; sometimes there is much sweating, and the sweat has a peculiar odour. The discharge from the genitals may cease; sometimes it does not, and the discharge is foul-smelling. The formation of milk is usually arrested. The bowels are loose, and the motions very offensive. The tongue becomes brown and dry, and little brown masses (*sordes*) form on the lips. Vomiting is frequent, the vomit being offensive. There is usually some amount of pain in the belly, which may become much swollen, adding to the distress. If muttering delirium sets in, and the patient's hands wander about picking at the bed-clothes, the case is as grave as can be. A very hurried feeble pulse, and rapid panting breathing, indicate sinking from exhaustion.

In other cases, at the very beginning of the fever, the patient complains of acute pain in one spot, usually low down in the belly, and the pain is apt rapidly to extend over the whole belly, which becomes much swollen, and is so painful that the mere weight of the clothes is distressing. To obtain some relief the patient lies on her back, with her knees drawn up. In such a case, instead of the bowels being loose, they are usually obstinately costive. Later on severe looseness of bowels sets in.

Treatment is too often utterly in vain. But if everyone were scrupulously careful cases of this disease ought to become exceedingly rare.

Moreover, the variety of the disease is so great that no one method of treatment is suited for each case. While stating this very strongly, we may even in such a very serious disease go on the same principle that pervades this book, and indicate general lines of treatment that may be adopted by any unfortunate enough to have no medical aid within reach. It is best to begin by clearing out the bowels with a large injection of tepid water, three or four pints. Nourishing food and stimulants must be freely given. Milk, eggs, nourishing soups, such as mutton soup, beef-tea, hough soup, &c., should be given in small quantities often, unless very loose bowels prevent much use of soups. Their loosening effect on the bowels may be to some extent checked by thickening them somewhat with corn-flour, &c. Whisky or brandy should be given in small quantities with milk to the extent of three or four ounces (one to two wineglassfuls) per day, if it seems to agree. Port wine is also useful and champagne. The fever is somewhat held in check by large doses of quinine, 10 to 15 grains every fourth or sixth hour; and to this may be added 10 grains of Dover's powder, if it seems to agree with the patient. If there is pain in the belly, a thick pad of flannel should be lightly wrung out of hot water, sprinkled with turpentine, and laid over the belly. This is kept on and repeated till the whole surface is red. If discharge from the genitals is fœtid, injections must be used with an enema syringe, fitted with a long delivery tube. Water, rendered pink with Condy's fluid, is employed to the extent of two or three pints, or carbolic acid solution of a strength of one ounce of the acid to two pints of water. This injection may be repeated twice daily. Great care must be taken that the injected fluid escapes freely. The patient's room must be freely but carefully ventilated.

STERILITY.

Sterility is want of the power of reproducing offspring, and is to be distinguished from impotence, which means inability for sexual intercourse. Sterility is not necessarily the fault of the wife. It may also be due to defect in the husband. In all cases it is desirable that this should not be overlooked, though here only sterility in the female will be considered.

In the first place, it may be that the sexual act is not duly performed. This is more frequent than might be supposed, for neither husband nor wife cares to consult even the medical attendant when the act of intercourse is attended with difficulty. Such a condition is called **dyspareunia.** Sometimes the genital passage of the female is so narrow, either naturally or as the result of inflammatory contraction, as to cause the difficulty, or the presence of painful spots or excrescences renders the act so painful that it is discontinued. The writer has treated such cases, in which this condition had existed for years without any remedy being sought, because of the idea that relief could not be obtained. It should, therefore, be plainly stated that this idea is in many cases erroneous, and that often a cure is easy of accomplishment, involving no severe or heroic method of treatment. Supposing, however, the sexual act to be duly performed, and supposing no defect to exist in the husband, the intercourse may be barren, from a variety of causes. The cause may lie in the ovaries

(p. 480), where the ova are developed, or in the tubes (fallopian tubes, p. 480), down which the ova should be conducted to the womb, or in the womb itself, or in the genital passage.

In rare cases the ovaries are absent or imperfectly developed, and do not perform their function of producing the female element in the reproductive act. It may be that the ovaries have been mature, but have been destroyed by inflammatory or other disease. In some cases the ovaries are displaced, and the ova are ripened but do not find their way to the fallopian tubes. Inflammation may have blocked the tubes so that the ova cannot pass down to the womb. Again, the fault may exist in the womb, which, in very rare cases, is altogether absent or has never grown to maturity. More commonly displacement or inflammation of the womb is a cause of sterility, the displacement preventing the due meeting of the male and female element in conception, and inflammation rendering the womb unfit for its duty of receiving and retaining an ovum which has undergone the changes of conception. In many cases the discharge from a womb that is the seat of such a disease is destructive to the life of the male element, and conception is thus prevented. In other cases of sterility tumours of the womb are the cause. Sometimes the cause is a very contracted state of the mouth and neck of the womb preventing the passing upwards of the fluid from the male. An inflammatory condition of the genital passage, specially such as is attended by a profuse discharge, produces sterility by the injurious effect of the discharge on the semen from the male.

Treatment in each case depends on the cause of the failure. Displaced and inflammatory conditions of the womb, as well as contracted states of the neck and mouth of the womb, &c., are all open to treatment, and the treatment in many cases is attended by the desired result. But women ought to be warned to trust only the opinion and advice of well-informed and conscientious physicians.

NERVOUS DISEASES OF WOMEN.

Hysteria, Catalepsy, and Trance.

Hysteria (Greek *hustera*, the womb).—This is so remarkable and amazing a disease, having so many varied forms, and producing so many perplexing manifestations, that it is doubtful if any but the briefest notice of it is necessary in a work like this. It is a puzzle and plague to nearly every physician. It is apparently due to a peculiar nervous condition, not necessarily attended by any structural change or disease in the nervous organs. It does occur rarely in men, but is very common in women, most frequently between the ages of fifteen and thirty, and specially between the ages of fifteen and twenty. Very commonly it is associated with some disturbance of the genital organs, often slight in itself, but sufficient in the case of nervous girls to excite the manifestations of the disorder. In those liable to nervous disturbance it may be induced by too luxurious and indolent habits, by unfortunate surroundings, badly directed training, and various other causes. The fact that men are, though rarely, affected with hysteria, is sufficient proof that it is not necessarily related in women to the genital organs. Yet it must never be overlooked that some disorder, perhaps slight, of the organs of generation may be the exciting cause in women. In those liable to it, some such disturbance may occasion an attack, and the continuance of the condition may cause repeated recurrences of the attacks for a prolonged period. It is always, therefore, desirable to make sure that there is no such exciting cause at work, and this can only be done by a skilled physician.

Symptoms.—Hysteria may produce symptoms referred to every organ of the body. Symptoms related to the digestive organs are frequent, such as loss of appetite, obstinate vomiting, costiveness, excessive development of gas in the bowels. Disturbance of the heart, fainting, &c., are common. Spasmodic seizures and fits of various kinds are of common occurrence. It is a spasmodic contracting of the throat, often excited by flatulence, that gives rise to the feeling of a ball in the throat common in hysteria, and which has been called *globus hystericus.* Paralysis of the legs, loss of voice and speech, loss of feeling in various parts of the body, may all be the result of a hysterical condition. On the other hand, excessive tenderness of some parts is frequent. Hysterical neuralgia, pain in a joint, in the breast, in the head, or over the stomach, are common. The determination of the true nature of these disturbances is a matter of great difficulty. The mental condition of hysterical persons is also peculiar. They are nervous and excitable, prone to laugh or cry at trifles, with little control over their emotions, irritable, querulous, and quarrelsome.

Treatment.—The main element in treatment is firm and judicious control. If the person can

be removed from the care of anxious friends and placed entirely under the discipline of strangers, much benefit will result. Hysterical convulsions can usually be cut short by dashing quantities of cold water about the person's face.

Catalepsy is a peculiar nervous condition, in which the patient loses all consciousness. At the same time the muscles of the body become so stiff, that if a limb be placed in any position, no matter how unusual or difficult to maintain in ordinary circumstances, that position will be kept for a considerable length of time. The condition may last from a few minutes to several hours; and it may pass off suddenly or slowly. It is met with usually at the same age as hysteria, but it has occurred at as early an age as 5 years, and also in advanced life. During the attack the face is without expression and pale, and the movements of breathing are slowed, as also is the action of the heart.

The patient retains the position in which she was when seized. The muscles become rigid, and after this stiffness is overcome they become pliant, and can be moulded, as it were, like wax, into any position consistent with the integrity of the parts. This position will be maintained till the muscles become exhausted.

The surface of the body may become so cold that, the pulse and breathing being barely perceptible, the condition may be mistaken for one of actual death.

Recovery is usually gradual. Attacks may occur at regular intervals, or irregularly and at long intervals; and they may last a variable time, from a few minutes to some hours.

Trance is a condition resembling sleep, which usually comes on suddenly, without any apparent cause, and from which the person cannot be roused.

It occurs chiefly in women between the ages of twelve and thirty. It is a rare condition. The subjects of it are usually hysterical, and it occurs in some cases as the result of exhausting disease, or excited by some emotional disturbance. It may last for a variable period, from several hours to many weeks or months. During its occurrence the countenance is pale, and the limbs are relaxed. No attempt at rousing produces return to consciousness, while the attack lasts. In most cases the mental functions are in abeyance; but sometimes the person knows what is going on, though unable to make the slightest movement. The action of the heart is diminished, and the breathing reduced. The bowels are moved, and water passed, as in health. When the trance lasts for a lengthened period, the patient partially rouses at intervals, takes food in a mechanical way, and then relapses into stupor. Recovery may take place slowly or suddenly. Most cases recover.

During the attack the nourishment of the person must be maintained by nourishing injections.

Ecstasy is a similar condition, in which, however, while the person is unconscious of impressions from without, the mind is possessed with some fixed idea, often of a religious character. The pulse and breathing are much reduced, the limbs remain in a particular attitude, and the countenance is pale, the eyes wearing a look of absorbed rapture.

PART II.

HYGIENE, OR A CONSIDERATION OF THE EXTERNAL CIRCUMSTANCES WHICH AFFECT THE HEALTH OF INDIVIDUALS AND COMMUNITIES.

INTRODUCTION.

The word *hygiene* is originally French, and means the science of health. It is derived from the Greek *hugieinos*, meaning "good for the health." It implies the study of everything outside of a person's own body which has an influence on his health. In the introduction to Part I., health has been viewed as the result of the harmonious co-operation of all the organs of the body in a sound condition. These we might call the internal conditions of health. It is clear, however, that if we limit our view to these internal conditions, we overlook a large number of circumstances which have an immediate and constant influence on the state of the body. Disease is more frequently due to a cause acting from without than to some condition originating from within. If, therefore, we are to have a fair all-round view of the conditions of health, we must give a careful study to the surroundings of a person, and observe how he is affected by them, we must study the conditions external to him, which directly and more or less constantly have a relation to his life. It is with these surroundings that the science of hygiene has to deal.

Now, the most striking of the outside agencies which constantly influence the bodily condition are the food a person eats, the liquids he drinks, and the air he breathes. These have already been considered (in Part I.), so far as was needful for our understanding of their general use within the body. But all details regarding, for example, the nature and composition of foods, the sources of foods, and the relation between their composition and their value to the human body, the varieties of liquids in common use, their varying properties and consequent effects upon the body, the various atmospheric conditions included under the term climate, and the influence they have upon human life, have been omitted in Part I. as foreign to the immediate purpose in hand. Yet they are all of the utmost importance. Again, the activity of the skin depends largely on the degree of heat and moisture of the external atmosphere, and the activity of the skin is remarkably related to the action of the kidneys, so that a change in the external atmosphere will profoundly affect the whole body. We can modify or alter the influence exerted by the atmosphere by the nature and amount of clothing worn. So it becomes of extreme interest to ask how and why clothing influences health. Further, while a person cannot voluntarily or directly affect the action of his heart, the activity of his circulation, or the rate at which his liver and kidneys remove waste from the body, he may indirectly but powerfully influence all these by the kind of work or exercise he engages in. Therefore the effects of exercise on health, whether in the form of work or play, become an important part of the study of hygiene.

In the next place we must remember how materially man alters the natural conditions of life, how very different, for example, may be the atmosphere he breathes from that he was, so to speak, designed to breathe, because of the nature of the dwelling in which he lives, because of the alteration of the composition of the air from the addition to it of foreign particles, produced by various kinds of industry, such as chemical works, or by metal grinding, such as brass grinding, &c., or because of additions to the air of organic impurities, such as are cast off from his own body in the course of its natural activity. So that in face of the ever-increasing developments of modern industry, the continual new departures which modern industrial progress renders necessary, and the new and unusual conditions of life they create, it becomes more and more a daily and urgent necessity that the principles of health should be studied, and their bearings on new conditions realized.

Every one who endeavours to arouse the public interest in such questions, and to direct the public attention to them, is met by the question, "How comes it that our forefathers

lived healthy and useful lives in spite of their ignorance of such principles, and how should we not be as healthy as they without such knowledge?" The answer is, that the tendency for men to mass themselves together in large communities has never been so marked as in quite recent times; and it is the formation of large communities and the growth of crowded cities that create conditions hostile to health, and render necessary the deliberate facing of the question how, in spite of such hostile conditions, health may yet be preserved. Men must be considered in the relationship they bear to one another, simply in virtue of their proximity to one another, and in view of the influence they exert on one another because of that proximity.

Each individual gives off organic material from his lungs, from his skin, from his kidneys, and from his bowels, which it is highly undesirable that his neighbour should get the benefit of, and exceedingly undesirable if he happens to be suffering from a disease, which may be communicated by such means, as many diseases may be (see Part I., section XIII.). In the ordinary course such organic materials would undergo destruction by natural agencies. In contact with the air they suffer oxidation or combustion, by which they are reduced to simple and harmless substances. Material cast off from the body and thrown upon the surface of the earth rapidly undergoes such combustion; discharged into the running stream, it is equally destroyed by the agency of the oxygen contained in the air dissolved by the water. Now, while "the self-cleansing properties of nature" are sufficient to effect their purpose speedily, where men live in scattered groups over a country, it is very different when men are so crowded together that the amount of air-space and earth-space for each becomes reduced to a minimum. To take an actual illustration, "there are ten rural counties in Scotland inhabited at the rate of only 41 persons per square mile, on the average of the ten years 1866–1875, while in Glasgow we endeavour to live in the proportion of 53,224 persons per square mile." Supposing the persons to be equally distributed over the square mile, then "in the ten rural counties each man, woman, and child enjoys an ample area of 16 acres, and is 296 yards from each of his or her neighbours; while in Glasgow each citizen is 'cribbed, cabined, and confined' within less than $\frac{1}{80}$th of an acre, and is only 8 yards from his nearest neighbours." In the former condition of affairs the amount of air-space and earth-space is sufficient to ensure the constant maintenance of healthy surroundings and the speedy destruction, by natural means, of waste organic products. In the latter case the amount of waste is so enormous that nature has no room to deal with it, and special means need to be devised for the removal from the community of the waste, whose accumulation means serious injury to health. One is, therefore, not surprised to learn that "in the rural counties only 17 per 1000 of these happy people die annually, while in Glasgow fully 30 perished in each of the years from 1866 to 1875. Shall we say that in Glasgow we choke and hustle each other out of existence?" (Dr. Russell). In proportion as men crowd together, in a similar proportion does disease multiply and the death-rate increase. So we get hold of "the idea, that vast as are the resources of nature, they are not without limits; and that as we add house to house, and man to man, in our cities, we had better have a care how we do it." Thus hygiene does not only study health in relation to the individual but in its bearings on communities, and we have the departments of private and public health established. Inasmuch, then, as each individual in a community may, by his mode of life, by its effects on his surroundings, seriously affect the welfare of his neighbours, and inasmuch as his neighbours may have no power themselves to put an end to his injurious influence, it becomes necessary to have some state regulation of the conduct of individuals in relation to a community, and there thus arises what is termed "State Medicine."

Hygiene, then, embraces within its scope not only the study of the principles of health in regard to the individual, the food he eats, the water he drinks, the air he breathes, the clothing he wears, the exercise he engages in, the dwelling in which he lives, the occupation at which he is employed, and the means by which the cast-off waste products of his body are removed from his immediate surrounding, but also, in regard to communities, the steps which are to be taken to prevent the accumulation of such waste products and the consequent spread of disease among the community, and such like questions.

In this portion of the book it will be our business to study food, drink, air, exercise, clothing, removal of waste, ventilation, drainage, &c., in their bearings on health, in an order such as has been indicated.

Section I.—FOODS.

Food and Energy:

The Meaning of Energy—Potential and Actual Energy;

The Sources of Energy; The Conservation and Transformation of Energy;

The Energy of Heat and of Mechanical Work—The Mechanical Equivalent of Heat

Food as a Store of Energy—The Energy obtained from various Foods by Burning.

The Chemical Composition of the Human Body:

Chemical Elements found in the Body;

Chemical Compounds found in the Body—Water, Inorganic Salts, Proteids, Starches and Sugars, Fats—Percentages of Proximate Principles of the Body.

The Nature and Chemical Composition of Food-stuffs:

The Classification of Foods—Proximate Principles of Food (Water, Salts, Proteids, Starches, Sugars, Fats);

The Fate of various Food-stuffs and their Uses in the Body.

The Composition of Animal Foods:

I. *Nitrogenous Animal Foods*—

Butchers' Meat—Beef, Mutton, Pork, Veal;

Various Parts of Animals—Liver, Kidney, Tripe, Bacon, Foie Gras;

Poultry and Game; Eggs;

Fish—Whiting, Haddock, Cod, Sole, Salmon, Herring, Mackerel, Eel, &c., Caviare, Poisonous Fish;

Shell-fish—Lobsters, Crabs, Oysters, Mussels, &c.;

Milk—Average Composition of Different Animals' (Cow, Ass, Goat, Mare, Sheep), compared with Human Milk—Characters of Milk and Variations due to Feeding, &c.; Cream, Buttermilk, &c.; Koumiss;

Cheese—Composition and Qualities of various kinds (Stilton, Cheddar, Gorgonzola, &c.);

Various Animal Foods Compared.

II. *Non-Nitrogenous Animal Foods*—

Butter, Lard, Dripping, Oleo-margarine or Butterine, &c.

The Composition of Vegetable Foods:

I. *Nitrogenous Vegetable Foods*—

Cereals or Grains—Wheat Flour and Bread, Food-stuffs made from Wheat (Semolina, Macaroni, Vermicelli), Oats and Oatmeal, Barley, Rye, Maize or Indian Corn, Rice, Millet, Buckwheat, Dari or Durra;

Leguminous Plants or Pulses—Peas, Beans and Lentils;

Tubers and Roots—Potatoes, Sweet-potato, Yam, Carrots, Turnips, Beet-root, Parsnip, Jerusalem Artichoke, Radishes, Salsify;

Herbaceous Articles—Cabbage, Cauliflower, Savoy, &c., Spinach, Celery, Rhubarb, Sea-kale, Onion, Asparagus, Lettuce, Endive;

Fruits—Cucumber, Vegetable Marrow, Tomato, Apples, Pears, Plums, Grapes, Figs, Dates, Bananas, Bread-fruit, Nuts and other Fruits;

Fungi—Mushroom, Morel, Truffles;

Sea-weed—Moss, &c.

II. *Non-Nitrogenous Vegetable Foods*—

Starchy Foods—Sago, Corn-flour, Arrow-root, Tapioca and Cassava, Tous-le-mois;

Sugary Foods—Sugar, Treacle and Syrup, Honey, Manna;

Vegetable Oils.

III. *Condiments.*

Comparison between Animal and Vegetable Foods.

The Adulterations of Food-stuffs, and Unwholesome Food.

The Digestibility of Food:

Time occupied in Digestion of Different Foods;

The Quantity of Different Foods that is Digested.

The Principles of Cooking.

The Construction of Dietaries:

Quantity of Food required per Day—Standard Diet, Starvation Diet,

Variations in Quantity caused by Age, Sex, Work, or Exercise;

The Regulation of Diet according to Season or Climate;

Diet for Training;

Economy in Diet—What Kind of Diet yields Everything required for Health and Work, at least cost?

Effects of Excessive or Deficient Diet;

Diet suitable for Special Bodily Conditions—Corpulence (Banting's System), Diabetes, Gout, &c.

Diets for Invalids and Infants—Beef-tea, Artificially Digested Foods, Analyses of Various Infants' and other Prepared Foods.

The Preservation of Food.

FOOD AND ENERGY.

The Meaning of "Energy."—The human body has already been compared to a steam-engine in working order. If the engine is to be kept working and in good condition two things are needful—(1), the engineer must repair regularly any tear and wear, the result of the working of the machine, and (2), a regular supply of fuel must be kept up to maintain the steam. The full meaning of the first of these conditions is plain enough; it will help us materially in arriving at a proper understanding of the nature and purpose of food if we consider more fully what the second implies.

The steam-engine, as it stands completed in the engineer's shop, may be a perfect instrument, and yet it will stand motionless and idle, till "the crack o' doom," unless something more be supplied to it. It possesses all the working parts, properly connected together, but it has no motive power. It lacks *the power of doing work*, that is it possesses no **energy**, for "energy" is defined as the power of doing work. How does the steam-engine obtain this power? It obtains it from steam at high pressure. Steam at high pressure possesses energy, energy stored up, so long as the steam is imprisoned in the boiler; but as soon as the steam is allowed to expand into the cylinder against the piston-rod, its energy is liberated, and appears in the form of mechanical movement, in the motion of the piston and the wheels to which it is connected. The energy, or power of doing work, stored up in steam at high pressure becomes transformed into energy liberated, work actually done, in the moving steam-engine as it lifts or transports the load attached to it. Thus we may have energy stored up, or as it is called **potential energy**, the power of doing work not in operation, and we may have energy liberated, **actual energy**, the power of doing work in actual operation. There are many illustrations of this difference between potential or stored energy and actual energy. A water-dam is a store of energy. The dammed-up water has the power of doing work, but so long as it is confined behind its barriers it remains only potential energy. If the gates are raised and the water allowed to flow away, its energy is liberated, and in its course to the sea may turn many mill-wheels, so that the potential energy of the dammed-up water becomes transformed into the actual energy of the mill-stones as they grind the flour. A wound-up clock-spring is another illustration of potential energy. While the spring is held by its catch the energy is stored, but as soon as the spring is permitted slowly to uncoil, its energy is liberated, becomes actual, and appears in the movement of the clock-work. Thus steam at high pressure, a head of water, a coiled spring are all illustrations of energy in the potential condition, capable of becoming changed into actual energy, as soon as the steam is permitted to expand, the water to seek the low level, and the spring to uncoil. The winds are illustrations of actual energy, energy being liberated, actual energy which is utilized by the sails of a ship or the arms of a windmill.

The Sources of Energy.—Now the question arises, where did the energy in each case come from? how does steam or a head of water or a coiled spring come to possess the power of doing work? Take the head of water to begin with. It is plain that its power of doing work is due to its position above the sea-level. As soon as it reaches the sea-level its power of doing work is gone. It is the mass of water in its course downwards to the sea that can do work. It is also plain that the higher the dam is above the sea-level, and the larger the quantity of water collected in it, the more work will be got out of it, the larger and the more numerous may be the mill-wheels which it will turn in its downward course. In short, if the height of the water above the sea-level be known, and the quantity of water in the dam, one could obtain an exact idea of the stored-up energy it represented, and of the amount of work that could be got out of the water in its descent. Suppose two dams, containing each the same quantity of water, but one only half the height above sea-level of the other, the water flowing from the high one would be able to do twice the amount of work done by the water from the low one. In short, the energy of falling water is the same as that of a falling weight, which depends on the amount of the weight and the distance through which it has to fall. The stored-up energy of a head of water may, then, be called potential energy *of position*, and the question, how did the water come to possess energy? will be answered if we can tell how the water came to be so high above the sea-level. The answer is easy. The water is the collected rain which has fallen. And what is the rain? Rain is originally vapour raised from the sea, &c., by the heat of the sun. The warm vapour passing through the atmosphere comes into contact with colder portions, clouds are formed, and finally the vapour is condensed by the cold and falls as rain. Collected in the uplands it

forms a head of water. It is the heat of the sun, then, that raised the water from the sea-level to the height, just as truly as a man may raise a weight from the ground and place it in a high position; and the energy of the head of water is really stored-up energy, which at a previous time had been liberated from the sun. The actual energy of the sun, as it does work in raising water from the ocean as vapour, becomes transformed into the potential energy of the mill-dam, and the potential energy of the mill-dam becomes re-transformed into the actual energy of the falling water as it turns the mill-wheel. When the water reaches the sea—and part of it before that—it may become again raised by the sun's heat in the form of vapour to fall as rain among the hills, and the circle of transformation may go on again. The power of doing work possessed by a head of water is thus derived from the sun. What of the energy of winds? Winds are due to differences of temperature in the air, the differences producing currents in the atmosphere. Take the case of the trade-winds. The sun's rays, beating directly upon the equator, heat enormous masses of air, which rise and flow north and south towards the colder regions of the poles, while colder currents flow in from both sides to the equator, become heated, and in their turn rise and spread outwards above. The energy of wind currents is thus also derived from the sun.

Let us think of the coiled spring, whence is its energy obtained? The spring was coiled by the strength of someone's hand. The person who turned the key expended energy, did work, in the act. But the energy liberated from the muscles of his hand and arm as he turned the key was not lost; it was being stored in the coiling spring, and would again be liberated in keeping the clock-work going. The energy of the person's muscle was derived from food consumed, and we shall see by and by (p. 528) that this energy too is in its origin traceable back to the sun.

Now let us return to the steam-engine; its energy is derived from pressure of steam, but how is the potential energy of steam at high pressure obtained? The steam is raised from water, placed in a boiler over a furnace in which fuel, let us say coal, is burned. It is the heat derived from burning coal that raised the steam so abundantly. So that the mechanical work done by the engine is derived, through pressure of steam, from the energy of heat. It appears, then, so far as the steam-engine is concerned, that the energy it liberates in doing work is derived from coal. The coal is the store of energy, a mass of potential energy, and, in the act of burning, its stored-up energy is liberated and appears, through the medium of the mechanical parts of the engine, as mechanical work. But how does the coal come to be a store of energy—what is coal? Of every pound of coal rather more than $\frac{3}{4}$ths consist of the chemical element called carbon. Now carbon has a strong attraction for oxygen gas, the chief gas in ordinary atmospheric air. When carbon and oxygen unite, there is formed a third substance, which, in ordinary circumstances, is a colourless gas. This union takes place with such force that an enormous quantity of heat is produced. If any two bodies are caused violently to clash together heat is produced by the force of collision. If cold iron be rapidly hammered on an anvil, in a short time it will be perceptibly warm. The particles of carbon having a strong chemical attraction for the particles of oxygen gas, as soon as they get the opportunity they rush together, and the collision of the uniting particles liberates heat. So, at least, we may explain it to our minds. To this process of uniting with oxygen the terms **burning, combustion,** or **oxidation** are applied. If we were to express in scientific terms such an ordinary everyday fact as that "the fire burns," we might say "the coal is undergoing oxidation in the grate." It is not necessary to speak by the card in this way, but it is very necessary to remember that, when the fire burns, what is really happening is that the carbon, of which the coal mainly consists, is uniting with the oxygen contained in the air, with the result that carbonic acid gas, among other products, is formed and escapes up the chimney, and a great amount of heat is given off by the force of the chemical combination. In the case of coal the union with oxygen needs encouragement to begin with, and the needed encouragement is afforded by applying a light to the coal. Once it has made a start it goes on, however, vigorously, provided the supply of oxygen is plentiful, provided, that is, there is plenty of air, and a draft of air to bring fresh supplies to the fire. Everybody knows that, if the chimney "will not draw," the fire goes out, that is, there is not sufficient draft to bring fresh supplies of air (which contains the oxygen) quickly enough to permit the union to go on. If the fire is languishing, someone goes for the bellows and speedily blows the fire into a blaze; that is, by means of the bellows large quantities of oxygen are quickly driven into the fire, and the rate

of chemical combustion is so much increased that the heat becomes very great. It is in this process of union with oxygen, then, or oxidation process, that heat is liberated; and heat is liberated wherever that process occurs. The heat may not be perceptible if the process is slow, but wherever the process is very rapid the heat is great. We are thus enabled to understand that the energy of heat as thus derived is the result of the energy of chemical attraction.

But we have not yet answered fully the question of the source of the energy of coal. How did carbon come to be in the form of coal? Coal is derived from vegetable matter. Beds of coal were originally masses of vegetation, perhaps in some primeval forest. The vegetable matter has become covered over, and, under the influences of temperature, moisture, and pressure, chemical changes have gone on in the slow course of ages, which have resulted in converting the original plants, shrubs, and trees also, it may be, into masses of coal. The carbon, then, of the coal has originally formed part of the structure of a living plant. Now the carbon does not exist in the living plant in the simple form of the chemical element, but built up into highly complex compounds in the form of fats, oils, starches, and sugars. All these are compounds of carbon manufactured or built up by the plant in the course of its life. The plant obtains the carbon, which it thus builds up, from the atmospheric air, in which it exists in the form of the gas we have already mentioned, carbonic acid gas. That gas, we have seen, is a chemical compound of carbon and oxygen, and the plant seizes upon this compound in the air, splits it up, liberates the oxygen, retains the carbon and builds it up in its body into the complex fats, starches, &c. In this building-up process the plant does work, just as a man does work in lifting a weight or coiling a spring, and the energy it thus expends is stored up in its body in the starch or fat it has manufactured, just as a man stores up the energy, expended in lifting the weight or coiling the spring, in the weight he has lifted or the spring he has coiled. The plant, therefore, stores energy in the complex carbon compounds it produces. Where did the plant get the energy to do this? It has been shown that the plant can only separate carbon from the atmosphere and build it up in its own body *under the influence of the sun's rays.* Unless the sun's rays were poured upon it it would cease to do this and die. In the end it comes to this, then, and this is the important point, that the energy of the plant is derived from the sun, and that the energy of the sun's rays is stored up in the plant in the form of fats, oils, sugars, and starches, and such carbon compounds. This stored-up energy becomes, under the influence of temperature, pressure, &c., already referred to, the stored-up energy of coal. When we burn coal we liberate, by the agency of chemical combination, the energy which, countless years before, the plant had stored up from the sun's rays, and, by appropriate means, convert it into the energy of steam at high pressure, and then obtain it as work done in the form of mechanical motion.

Thus we find the energy of a head of water, of currents of air, and of coal, are ultimately derived from the sun, from which source there thus really proceeds practically all the power of doing terrestrial work.

In the case of coal we see a remarkable circle of changes similar to that observed in the case of a head of water. The plant stores the energy of the sun; in time the stored energy reaches us as coal. We burn the coal and liberate the energy. In this act carbonic acid gas is formed and passed into the atmosphere. The plant seizes upon the gas and under the influence of the sun again converts the carbon into a store of energy, to be again liberated, and so on.

Further, we have traced the building up of fats, oils, starches, and sugars in the plant to the energy of the sun. But these form a large portion of man's food, and the exclusive food of animals used by man for food—the ox, sheep, &c. The food of man is then the stored-up energy of the sun, which man takes into his body. In his body he liberates that energy in the form of heat and mechanical work, so that the energy he expends in lifting a weight, coiling a spring, &c., is energy derived originally from the sun.

The Conservation and Transformation of Energy.—In the preceding paragraphs we have had illustrations of the fact, the discovery and proof of which form one of the chief triumphs of modern science, that energy is never lost. When energy seems to disappear, in reality it does not do so; it simply assumes another form. The energy of chemical action may become transformed into the energy of heat, that of heat may assume the form of mechanical work. The energy expended in the form of mechanical work, as in lifting a weight, is not lost, but becomes potential energy of position, for the weight as it descends may do work or liberate heat and so on. Thus we have an idea of what is meant by the modern law of the

conservation of energy, the law which states that energy is never lost, and also of what is meant by the transformation of energy, which explains what takes place when energy seems to disappear. The right understanding of this is of the utmost importance in our study of foods.

The Energy of Heat and of Mechanical Work.—Let us return again to our illustration of the steam-engine. We have seen that the power of doing work possessed by the steam-engine is obtained from the coal in the form of heat. If it is true that energy is never lost, and if we suppose our engine to be a perfect one, so that all the heat given off from the coal is converted into work done by the engine, then the amount of work which the engine can do ought to be exactly measured by the amount of heat given off from the coal. Is this true? Does a certain amount of heat always represent a certain amount of mechanical work, so that given a certain amount of heat, one can calculate from it the amount of mechanical work, assuming that all the energy of heat is converted into work done? There is such a definite relation, and it was proved by two men, working independently of one another, Julius Robert Mayer (1842), a Schwabian physician, and James Prescott Joule (1845–1847), a manufacturer of Manchester. To determine the relationship, it is plain one must have to begin with standards of measurement for heat and work done, just as to determine the weight of any body one must have a standard of weight, namely, the pound weight. The standard measure of heat is the amount of heat necessary to raise the temperature of one pound weight of water at the freezing-point one degree on the Fahrenheit scale. This amount of heat is called the unit of heat, and is called the **calorie**, as the standard of weight is called the pound, or the standard of length the yard. Ten pounds weight of water heated by 1 degree Fahrenheit represent 10 heat units, or 10 calories. The standard of work is the amount of work done in raising a weight of 1 pound 1 foot high. This is the unit of work or the **foot-pound**. When a man raises a weight of 1 stone 1 foot high, he is said to do 14 foot-pounds of work, and if he raises 2 stones (28 pounds) 10 feet high, he does 280 (28 multiplied by 10) foot-pounds of work. Now, the question is, is there any exact relation between the calorie, or unit of heat, and the foot-pound, or unit of work? for if there is, it will be necessary only to measure how many units of heat are given off from the burning of 1 pound of coal to determine how much mechanical work can be got out of the energy thus liberated from the coal. Now, we have said that a man expends energy in raising a weight to a certain height, and the quantity of energy depends on the weight and the height to which he has lifted it; and further, that the energy thus expended is stored up in the weight; when the weight is allowed to fall the energy is liberated. If the weight have a cord attached to it and the cord be wound round some piece of clock-work, the liberated energy will be employed in doing work. If a weight of 10 lbs. be raised 50 feet, then it has stored up in it 500 foot-pounds of energy. Well then, to determine the relation between heat and mechanical work, Joule used an apparatus represented in Fig. 190.

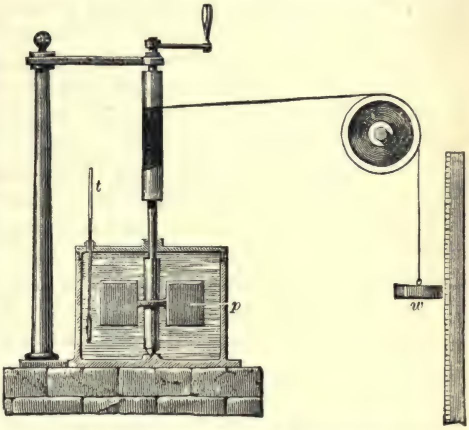

Fig. 190.—Joule's Apparatus for the Determination of the Mechanical Equivalent of Heat.

It consisted of a box in which, fixed to an axle, was a set of eight small paddles (p). The axle projected out of the box and had wound round it a cord, which passed over a drum, and connected to the cord was a certain weight (w). When the weight was allowed to fall, the drum revolved, the axle was turned and with it the paddles in the box. The box contained a weighed quantity of water, the temperature of which was taken. The revolving paddles agitated the water. A thermometer (t) fitted into the box dipped into the water. If the water became warmer the thermometer indicated the amount of heat. Joule allowed the weight to fall, causing the water to be churned, and then he found that, by the churning, the water was warmed. That is to say, the energy liberated by the falling weight, was transformed into the mechanical work of the revolving paddles, and that again was transformed into the energy of heat. Joule found that by a weight of 1 lb.

falling 772 feet, 1 lb. weight of water was raised one degree in temperature. That is to say, 772 units of work, or foot-pounds, were equal to 1 unit of heat or 1 calorie. We have seen that the energy liberated by a weight of 1 lb. falling 772 feet is the same amount of energy as is expended in raising 1 lb. 772 feet high. So that we might put the result thus: the amount of energy which, appearing as heat, will warm 1 lb. of water by 1 degree Fahrenheit, will, if converted into mechanical work, raise 1 lb. weight 772 feet in the air, or, what is the same thing, will raise 772 pounds 1 foot high. This number 772 is, therefore, called the **mechanical equivalent of heat.** In short, 1 unit of heat is equal to 772 units of work. If, then, a certain mass of coal yields 10 heat units, we can tell how much work it represents. Multiply by 772. The energy stored up in the coal, if all converted into mechanical work, will raise 7720 pounds 1 foot high, or 1 pound 7720 feet high. Similarly, if the weight of a ton has been raised 10 feet high, we can tell how much heat that represents. One ton is equal to 2240 pounds. That has been raised 10 feet, so that 22,400 foot-pounds of work have been done. But 772 foot-pounds are equal to 1 heat unit. Therefore 22,400 divided by 772 will give the amount of heat, in heat units, represented by the raising of the ton weight. It is equal to fully 29 heat units.

Here, then, is a means of determining the amount of energy stored up in any substance, such as coal, wood, oil, &c. It is only necessary to burn a given weight of the substance, say 1 pound, and to find how much water the heat produced will warm by 1 degree Fahrenheit. The figure obtained expresses the units of heat, or calories, yielded by the substance, and this, multiplied by 772, gives the mechanical work which the energy stored up in the 1 lb. of substance might perform, *supposing all the heat could be converted into mechanical work.*

Now, various observers have determined by experiments the amount of heat given off from very many different substances, so that there are now ready to one's hands the means of determining the value of these substances for the doing of work. The method by which the results were obtained it will be interesting to note. The instrument used to determine the amount of heat given off by a body in burning is called a **calorimeter**, or measurer of heat. It is represented in Fig. 191. It consists of a small chamber (C) within a much larger one (D). The space between the two chambers is filled with water, the quantity of which is measured. A thermometer (t) dips into the water to indicate the temperature. In the inner chamber is placed the substance to be burned. The heat given off in the process

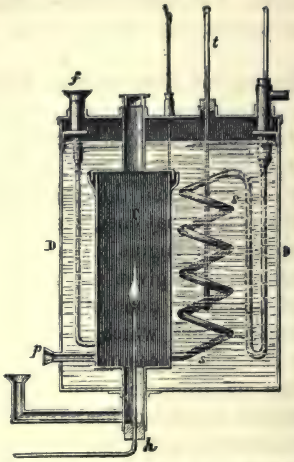

Fig. 191.—Dulong's Calorimeter for Combustion of Gases.
The gas to be burned enters by h, oxygen for combustion by f or p, and the products of combustion pass off by the worm s, s.

of burning is communicated to the water, various careful arrangements being made to prevent it being otherwise lost. When all the substance has been burnt, the temperature of the water is read off, and as the quantity of water is known, the units of heat are readily ascertained. It has been determined by such means that 1 lb. of wood charcoal, if completely burned, will yield 8080 heat units, that is will raise the temperature of 8080 pounds weight of water by 1 degree Fahrenheit. This heat we have seen is the result of the chemical union of the carbon, of which charcoal consists, with oxygen. Now, there is a gas called hydrogen, which, when chemically combined with oxygen, forms water. This gas burns. It is its presence in ordinary coal-gas that makes the gas burn. When hydrogen is burned with a stream of oxygen a flame of most intense heat is produced. It is this flame directed on a cylinder of lime that gives the intense light, the lime-light, so commonly used for magic lanterns. One pound weight of hydrogen when completely burnt yields no less than 34,460 units of heat.

We see, then, what an enormous quantity of heat is given off by carbon and hydrogen, and we have learned how, from the quantity of heat, we can determine the value of these substances for the production of mechanical work. Anyone who thoroughly understands this is provided with the means of estimating the value of different substances used as food-stuffs.

Food as a Store of Energy.—In the previous paragraphs it has been necessary to notice that fats, oils, starches, sugars, are built up by the plant out of chemical elements, which they obtain from the atmosphere and also from the soil. Now these different kinds of food-stuffs all consist of three elements, carbon, hydrogen, and oxygen, but arranged and combined in a highly complex way. We have seen, moreover, that the building up of these elements implies the expenditure of energy, and that the energy expended in the process is stored up in the manufactured substances. If these substances be broken down and reduced to their elementary form, the stored-up energy will be liberated. This breaking down can be effected by the process of oxidation or burning, by which the carbon unites with oxygen to form carbonic acid gas, and the hydrogen unites with oxygen to form water. The oxygen contained within the substances themselves is used for the process, but is not sufficient, and more requires to be supplied from without. In the oxidation process, whether it takes place rapidly or slowly, the stored-up energy is released in the form of heat, and from the quantity of heat liberated can be estimated, in the way already described, the value of the food-stuff for the production of mechanical work. This is true not only of the fats, starches, &c., that may be stored up in a plant, which, from one point of view, may be considered as something apart from the body of the plant itself, but is true also of the tissue of the plant itself, of the living matter or protoplasm of the plant, within which the living processes of the plant are accomplished. The protoplasm or living tissue of plants, as of animals, consists mainly of four elements, the three already named, carbon, hydrogen, and oxygen, and another of infinite importance, nitrogen, along with sulphur and sometimes phosphorus. If a plant be burned, the protoplasm becomes oxidized into carbonic acid gas, and water, and also into ammonia, the ammonia containing all the nitrogen, which had existed in the organized matter of the plant, the oxidation being accompanied as before by the liberation of energy in the form of heat. Animals feed on plants, some of them exclusively, and build up the compounds found in the vegetable food into still more complex substances in their own body, forming thereby muscle, blood, bone, fat and so on. Part of the food is never built up into the body of the animal, but stays in the body only long enough to be broken down into simpler and unorganized bodies, in order that the energy contained within it may be liberated for the use of the animal. Man consumes as food both vegetable and animal structures, uses it partly to build up the structure of his own body, and breaks part of it down into elementary substances in order to obtain from it the stored energy it contains. Food, then, whether animal or vegetable, consists of elementary substances built up into complex forms, and the energy which it thus contains may be liberated as heat by the process of burning. Various experiments, conducted by Professor Frankland, of the Royal School of Mines, and others, have been carried out for the purpose of accurately determining the value of different food-stuffs for mechanical work by the amount of heat liberated from them in process of combustion. The method adopted was that of the calorimeter already described. The following table gives the results obtained by Frankland. It expresses the amount of heat in heat units obtained by completely burning in the calorimeter 1 lb. of each substance named. The food-stuff was employed in its natural condition, that is without previous drying, unless when stated to the contrary.

Name of Food-Stuff.	Heat units per lb.[1]
Cod-liver oil,	9107
Butter,	7264
Cocoa nibs,	6873
Cheese (Cheshire),	4647
Bread-crust,	4459
Oatmeal,	4004
Flour,	3936
Pea-meal,	3936
Arrow-root,	3912
Ground rice,	3813
Yolk of egg,	3423
Lump-sugar,	3348
Commercial grape-sugar,	3277
Hard-boiled egg,	2383
Bread-crumb,	2231
Ham (boiled),	1980
Mackerel,	1789
Beef (lean),	1567
Veal,	1314
Guinness's stout,	1076
Potatoes,	1013
Whiting,	904
Bass's ale,	775
White of egg,	671
Milk,	662
Apples,	660
Carrots,	527
Cabbage,	434

[1] Frankland used the French thermometric scale, the Centigrade scale. To heat 1 lb. of water by 1° on the Centigrade scale requires 1389 units of work, while, as we have seen, 772 is the figure for the Fahrenheit scale. To convert heat units on the Centigrade scale, therefore, *multiply* by 1389, and to convert units of work into heat units on the same scale *divide* by 1389.

By performing the appropriate calculation we might express the value of the energy liberated from each substance in terms of mechanical work. Thus from these figures we find that the total energy liberated from 1 ounce of butter would, if all could be converted into mechanical work, raise 281 tons 1 foot high.[1] Other illustrations are given in the table.

1 ounce of	butter is equal	to	281	tons raised 1 foot.
,,	oatmeal	,,	152	,,
,,	beaf (lean)	,,	55	,,
,,	milk	,,	24	,,
,,	carrots	,,	20	,,
,,	cabbage	,,	16	,,
	&c.		&c.	

If one carefully examines this list, one or two points of great interest speedily reveal themselves. The first glance shows that fats and oils head the list, they yield the greatest amount of energy. Cocoa nibs rank very high; but when we examine the composition of cocoa nibs we find they contain 50 per cent of fat, so that it is really because of their contained fat that they have so great value as stores of energy. Next to the fatty substances come the starchy. Arrowroot consists mainly of starchy material, while flour consists of starch to the extent of nearly 75 per cent, and meal to 63 per cent. If we ask how oatmeal has a higher value than flour or arrow-root, the answer is that oatmeal contains also 10 per cent of fat, while flour contains less than 1 per cent, and arrow-root contains none. It is, then, the fat in oatmeal that causes it to rank above flour, &c., as a store of energy. Again look at the difference between yolk of egg alone and the whole egg in the amount of energy they yield. Here again it is a question of fat. In the yolk of egg there is 30 per cent of fat, but when one takes white and yolk mixed, as the white contains no fat, the percentage of fat in the whole is reduced to 11. Thus 1 lb. of yolk is of more value, as a store of energy, than 1 lb. of mixed white and yolk. It is a similar circumstance that gives to mackerel a higher value as a store of energy than is possessed by whiting. Mackerel contains fully four times the quantity of fat that whiting does. Thus the list shows that, regarding food-stuffs as stores of energy, fats take the highest rank, starchy and sugary food-stuffs come next, and meaty substances (lean beef), &c., are poorer in the amount of energy they yield than either. This has been further shown by the results of actual experiments on dogs, in which it was found that

100 parts of fat yielded as much heat and energy for work as
232 ,, ,, starch,
234 ,, ,, cane-sugar,
and 243 ,, ,, lean meat.

Is there any reason for this high value of fat as a source of energy? When fat is analysed it is found that of every 100 parts

79 consist of carbon, and
11 ,, of hydrogen

and only 10 of oxygen. That is 90 of the 100 parts are combustible or oxidizable substances. Starch, on the other hand, contains in every 100

45 parts of carbon and
6 ,, of hydrogen,

a total of 51 parts only of combustible substance, the remaining 49 consisting of oxygen with which the burning is partly effected. Sugar consists of

43 parts carbon, and
6 ,, hydrogen

in the hundred, a total of 49. The enormous quantity of heat liberated by the burning of carbon and hydrogen has been already indicated (on p. 530), and when we find fat containing 90 parts in 100 of these elements as against 51 in starch and 49 in sugar, the reason of the high value of fat as a source of energy is apparent.

Now it will naturally occur to everyone, who considers the figures that have been given, that the amount of energy represented as mechanical work given off, from the burning of the food-stuffs named, is too great for belief. It seems absurd to think that 1 ounce of butter will yield heat, which, if transformed into work done, will raise 281 tons 1 foot high. The amount of heat stated is actually given off, and has been determined, as stated, by actual experiments in the calorimeter. In estimating the mechanical work that heat represents, it has been assumed that *all the heat is transformed into mechanical work*. But, as a matter of fact, no engine has been devised, or can be devised, capable of utilizing all the heat obtained from the burning of the fuel, and converting it into mechanical work. In the most perfect machine yet constructed it has been found possible to convert

[1] 1 lb. of butter gives 7264 heat units. To get the equivalent in mechanical work, multiply by 1389. The result is 10,089,696 in foot-pounds per *pound* of butter. That is equal to 630,606 foot-pounds per *ounce* of butter. 630,606 divided by 112 expresses the same amount in hundredweights, namely 5630; and that again divided by 20, expresses the amount in foot-tons, namely 281.

only ⅙th part of the heat into work. It is the aim of engineers to construct engines that will utilize as much of the heat as possible, and yet this is the best result they have obtained. They do not wish the engine to become heated, for that means wasting the energy of the fuel. In the animal body the energy derived from food is converted into mechanical work to a much greater extent than can be effected by any steam-engine. It has been estimated, for example, that the horse can transform 32 per cent of the energy obtained from food into work, that the ox can transform 43 per cent, and man can transform 53 per cent. So that in this respect the human body is far ahead of the most perfect engine that man has yet been able to construct. But, in the case of the animal body, the energy of food that appears as heat, and is not transformed into work, is not lost. It is necessary to heat the animal body and to maintain its warmth at a certain degree, which is usually higher considerably than that of the external temperature. Because the body is continually in contact with an atmosphere colder than itself, a large quantity of heat is continually being given off from the body. Heat is constantly being lost in the evaporation of the sweat, in heating the air given out from the lungs, in heating the discharges from the body, &c. The quantity of energy consumed in this way, in 24 hours, has been calculated as equal to 2,839,000 units of heat, or a heat sufficient to raise about 62 pounds of water from freezing-point to boiling point (Gamgee). But energy is not only being constantly expended in the body in this way, it is also being expended in large amount in doing work of which there is no external sign. The heart is regularly contracting, driving the blood through the body. The work it does "might be estimated without exaggeration as at least equal in 24 hours to the work expended in lifting 120 tons to the height of 1 foot, while almost certainly it would greatly exceed this estimate. That is to say, that the heart of a person, who is almost absolutely at rest, does an amount of work which is a sensible fraction of the *external*, or, to use a popular expression, the *manual* labour performed in the working day of a hard working labourer." Over and above this, there is the work being regularly done by the muscles of respiration in expanding the chest against considerable resistance. If all these things are taken into account, it will become apparent that there will not be left over a very large balance of energy derived from the food for the performance of external work. Moreover, one must not forget that when a man simply walks about he is transporting the weight of his body, and when he walks up a stair he is raising the weight of his body so many feet into the air. Thus a man weighing 11 stones (154 lbs.) going up a step 6 inches high, does 77 foot-pounds of work in carrying up his body, and if he goes up a stair of 12 steps 20 times a day, in this exercise alone he does 16 foot-tons of work. The same man in walking one mile does nearly 17⅘ foot-tons of work in the mere transporting of his own weight.

All this time we have been arguing from figures derived from the burning of food-stuffs in the calorimeter. It is time now to say that it appears that food-stuffs undergo a precisely similar change in passing through the body to that they undergo in the calorimeter. The change, that is the combustion or oxidation process, as carried on in the calorimeter, is very much more rapid than the change as accomplished in the body, but the results are the same. Fats, starches, and sugars, are burnt to carbonic acid gas and water in the body, just as they are outside of the body, and the carbonic acid gas and water are, thereafter, expelled from the body as waste products. Whether the process be rapid or slow, the total energy liberated, when the process has been completed, is the same. The figures derived from the calorimeter may, therefore, with perfect propriety, be applied to the human body. There is an exception. Meat does not undergo complete combustion in the body. The figures obtained from the experiments are, in consequence, too high for it. Corrections for this are, however, easily made. This it is not necessary for us further to consider.

Now we must return once more to the illustration with which this section opened. We said the human body could be compared to a steam-engine in thorough working order, and that to maintain it in good condition it was necessary (1) for the tear and wear of its parts to be maintained, and (2) for energy to be imparted to it for the doing of work. We have seen that the energy is derived from the combustion of coal in its furnace. This induced us to consider the nature and sources of energy, and we naturally went on to consider food as a source of energy to the human machine, for the human body may also be viewed as a machine for doing work. In the doing of work some of its parts are subject to tear and wear, which, if the human machine is to be kept in good working order—that is, in good health—must be speedily re-

paired. In the second place, it must be supplied with energy.

This, then, is the twofold business of food, (1) to repair the tear and wear of the human machine, and (2) to yield energy by which it may do its daily work. Having seen, generally, how food is fitted to yield energy, we must next notice how food is fitted to repair tear and wear. Suppose a steam-crane is engaged lifting heavy loads for an hour on end. During the process two things have happened; (1) steam has been allowed to escape from the boiler into the cylinder to work the piston—that is, energy has been liberated, and to a slight extent—a very slight extent—the working parts of the machine have been worn. The energy for lifting the weight has not been obtained from the wear and tear of the machine, but from the steam. Now substitute a man for the steam-engine, and suppose him to work for an hour on end wielding a heavy hammer. He has lifted the hammer regularly by the repeated contractions of some of the muscles of his arm, and in these muscles two things have happened; (1) energy has been liberated within the muscles by the combustion or oxidation or burning of some substance contained in the muscles, and (2) the muscles, to a slight extent—a very slight extent—have been worn. That is to say, while the muscles have actually suffered some wear and tear by this work, the energy liberated in the muscles need not have been produced by the breaking down of some of the actual fibres of the muscle, but only of some substance contained within the muscle. It is plain, then, that there may be some considerable difference between supplying the material out of which energy is obtained and the material out of which the wear of the muscle is repaired. Whether there be any difference or not, there is only one source from which both kinds of material are obtained, and that source is food supplied. It is also perfectly plain that if the food supplied is to be sufficient for the rebuilding of wasted muscle, it must contain all the materials of which muscle is found to consist. The same is true of every other part of the body. In the working of the bodily machine the bones suffer some tear and wear. It may be slight, but the wear and tear, nevertheless, occur, and the food supplied must contain the elements of which bones are made. Nerves suffer waste, and every tissue of the body; and thus food must contain all the elements of which every organ and tissue of the body are built up. If it does not, some tissue of the body will not be supplied with material for repairing its wasted portions, and a catastrophe will, sooner or later, occur. In order to understand what kind of food is fitted for such purposes, we must, therefore, have some kind of knowledge of the composition of the human body.

THE CHEMICAL COMPOSITION OF THE HUMAN BODY.

Chemical Elements found in the body.—All the various complex substances found in nature can be reduced by chemical analysis to simple substances, and when they have been reduced to their simplest forms and cannot be any further split up, there remain seventy elements. By combinations of these seventy elements, of various kinds and in various proportions, all the substances known to exist in the world of nature are built up.

A human body, when dead, may be submitted to chemical examination just as a handful of earth, a piece of rock, or any other substance may be. When that has been done it is found that blood, muscle, nerve, bone, skin, hair, teeth, &c., may also be reduced to similar elements—that, in fact, the human body is built up of a few of the same seventy elements that are found in nature. Of the seventy elements only fourteen are found in the human body, namely, **oxygen, hydrogen, nitrogen, chlorine, fluorine, carbon, phosphorus, sulphur, silicon, calcium, potassium, sodium, magnesium,** and **iron.** Some of these elements, as they exist in their elementary form, are gases, others are metals, while the remainder are non-metals. This may be shown as follows:—

Elements found to exist in the Human Body.

Oxygen Hydrogen Nitrogen Chlorine Fluorine.	Gases.
Calcium Potassium Sodium Magnesium Iron	Metals.
Carbon Phosphorus Sulphur Silicon	Non-Metals.

Besides these, excessively minute quantities of other elements, such as manganese, copper, lead, &c., have been found, but probably they are only accidentally or temporarily present, and did not enter into the actual constitution

of the body. They may, therefore, be neglected. Silicon is in a similar position though it appears on the list.

It is interesting to note the proportion in which these various elements are present, and that is shown in percentages in the following table:—

Oxygen ...	... ...	62·430 per cent.
Carbon ...	... ...	21·150 ,,
Hydrogen	... ...	9·865 ,,
Nitrogen	... ...	3·100 ,,
Calcium	... ...	1·900 ,,
Phosphorus	... ...	0·946 ,,
Potassium	... ...	0·230 ,,
Sulphur ...	... ...	0·162 ,,
Chlorine	... ...	0·081 ,,
Sodium ...	... ...	0·081 ,,
Magnesium	... ...	0·027 ,,
Iron ...	... ...	0·014 ,,
Fluorine	... ...	0·014 ,,
		100·000

Oxygen, hydrogen, and nitrogen, as we see from the preceding table, are gases in their uncombined state, and yet they form three-fourths of the weight of the whole human body. Carbon is a solid. Charcoal, lampblack, black-lead, are impure forms of it. It forms more than a fifth of the whole weight of the body. Carbon and the three gases named thus form over 96 per cent of the total weight of the body.

Chemical Compounds found in the body.—It is necessary very carefully to note that, with slight exceptions, none of these elements exist *in their elementary form* in the body; they are combined with one another in various ways and proportions to build up more or less complex substances, differing widely from the elements of which they consist. The slight exceptions are oxygen, hydrogen, and nitrogen. Though the bulk of all three exists in combinations of various kinds, yet a small quantity of oxygen exists uncombined, but in solution, in the blood, a small quantity of nitrogen is also found in solution in the blood, and small quantities of all three exist free in the intestinal canal.

Water.—Now oxygen and hydrogen unite to form water; and water is found in the human body to the extent of over 60 per cent.

Inorganic Salts.—Further, a large number of the elements named are found uniting with one another to form inorganic salts, salts found existing in nature, which do not need the agency of any living thing, any organized structure, to cause them to combine, but do so simply by the force of chemical affinity.

The best example of this kind of compound is common salt, a compound of sodium and chlorine, called, therefore, in chemical language, chloride of sodium. It is found in all the tissues and fluids of the body, and is one of the most important inorganic substances the body contains, and is absolutely necessary for continued existence.

Chlorine, besides uniting with sodium, forms a salt in conjunction with potassium, the chloride of potassium, and forms, with nitrogen and hydrogen, the chloride of ammonium, ammonia being a compound of nitrogen and hydrogen. These are found in the body.

Other salts are found in the body, of great importance being those formed by a combination of phosphorus with sodium, with potassium, with calcium, and with magnesium, forming the phosphate of sodium, phosphate of potassium, phosphate of magnesium, and phosphate of calcium (phosphate of lime). This last, phosphate of calcium (that is, phosphate of lime), is the most abundant of the salts of the body. It forms more than half of the bones, and is found in considerable quantity in teeth, and it exists in other solids and in fluids of the body. It is present in milk to the extent of 2½ per cent. Associated with it in bones and teeth is a compound of calcium with carbon and oxygen, carbonate of lime.

Sodium combined with carbon and oxygen exists in the body as carbonate of sodium, and with sulphur and oxygen as sulphate of sodium.

Potassium also exists as sulphate of potassium.

Fluorine and calcium are found united as fluoride of calcium in the bones and teeth, though in very small amount.

If all these compounds, forming salts or mineral matters, that exist in the body, be summed up together, they are found to constitute about six per cent of the whole body weight.

Thus, so far as we have gone, we see the human body consists of:—

Water about	... ...	61 per cent.
Salts or Mineral Matters	...	6 ,,

Namely—*Chloride of Sodium.*
„ of Potassium.
„ of Magnesium.
„ of Ammonium.
Phosphate of Lime.
„ of Sodium.
„ of Potassium.
„ of Magnesium.
Carbonate of Lime.
„ of Sodium.
Sulphate of Potassium.
„ of Sodium.
Fluoride of Calcium.

A compound of hydrogen and chlorine, hydrochloric acid, is found existing as such in the digestive juice of the stomach.

Organic Compounds.—Now, over and above these substances, there exists in the human body a series of compounds not found in the lifeless or inorganic world, substances formed of the union of the same elements that have been named, but which require for their compounding the agency of living structures. For that reason these compounds are called **organic.** Moreover, man and the lower animals cannot compound them, or build them up from the elements. That is done by plants. Man and the lower animals take the organic materials they require from the vegetable world, and so the structure of the animal kingdom, including man as the most imposing portion of the edifice, rests upon the vegetable kingdom as its foundation. The organic materials which animals and men take from the vegetable kingdom they build up into still more highly organized forms in their own bodies.

The organic materials found in the human body fall principally into three classes:—

Proteid or Albuminous Substances.
Carbo-hydrates (that is, Starches, Sugars, and Gums).
Fats.

The elements built up into proteids are carbon, hydrogen, oxygen, and nitrogen, with sulphur; the elements built up into carbo-hydrates are carbon, hydrogen, and oxygen; the elements built up into fats are also carbon, hydrogen, and oxygen. The important distinction between the first and the other two classes is that proteids contain the element nitrogen which the others want. Proteids are, therefore, called **nitrogenous,** and the others **non-nitrogenous** substances.

Further it will be noted that both the carbo-hydrates and the fats are built up of the same three elements, carbon, hydrogen, and oxygen. Though formed of the same three elements, these two classes differ markedly from one another. The difference between the two consists, for one thing, in the very widely different proportions in which the elements are combined in the two kinds of food-stuffs, a difference which chemistry can reduce to figures. But it also consists in the manner in which the elements are combined, just as stone, wood, and lime may be built up into two houses of very different form, and not the least resembling one another. It may now be convenient to put in tabular form the knowledge thus far gained.

The human body contains thirteen elements built up into various compounds, as follows:—

Inorganic—

		Built up of
	Water	Hydrogen and Oxygen.
	Salts	Hydrogen, Oxygen, Nitrogen, Carbon, Calcium, Phosphorus, Potassium, Sodium, Sulphur, Chlorine, Magnesium, Iron, Fluorine.

Organic—

Nitrogenous	.........Proteids ...	Carbon, Hydrogen, Oxygen, Nitrogen, Sulphur.
Non-nitrogenous	Carbo-hydrates	Carbon, Hydrogen, Oxygen.
	Fats	Carbon, Hydrogen, Oxygen.

We must consider the organic substances for a little.

Proteids consist, as already mentioned, of carbon, hydrogen, oxygen, nitrogen, and sulphur. The type of proteids is egg albumin, white of egg. These proteid or albuminous bodies are found in muscle, in nerve, in glands, in blood, and in nearly all the fluids of the body. The albuminous body of muscle is called **myosin,** that of the fluid part of blood is **serum-albumin,** that of coagulated blood is **fibrin,** the red corpuscles of the blood are formed of **hæmoglobin**, which contains an albuminous body.

Milk contains two albuminous bodies, the chief of which is **casein,** which forms the curd, and is the main constituent of cheese. Proteid bodies occur in various forms in vegetable structures; the proteid of cereals, wheat, corn, &c., is called **glutin,** that of peas is **legumin.**

Other forms of proteids exist. Thus, in bones, and connective tissues like tendon and skin, a proteid body exists which, on boiling, yields **gelatin.** Gristle (cartilage, p. 23) yields another proteid called **chondrin.**

Of proteid substances a human body is estimated to yield on an average about 18 per cent.

Carbo-hydrates are formed of carbon, hydrogen, and oxygen, the last two being in proportions to form water. Starch is a carbo-

hydrate, and is found in the body in the form of **glycogen** or animal starch, supposed to be formed by the liver (see p. 147). Sugar is another of this class, and is found as **grape-sugar** in blood and liver, **muscle-sugar** or **inosite** in muscle, and **lactose** or **milk-sugar** in milk.

This class exists largely in the vegetable kingdom. Thus potatoes, rice, sago, &c., consist largely of starch. Sugar is found in fruit as **laevulose**: there is **grape-sugar**, of which honey mainly consists, derived from the sweet juices of fruits and flowers, and **cane-sugar**. **Gum** and **cellulose**, obtained from plants, are also carbo-hydrates.

The carbo-hydrates in the body are estimated at a fraction of one per cent of the total body weight.

Fats are formed of carbon, hydrogen, and oxygen, in which the two latter are not in proportions to form water. There are three kinds of fat in the body—**stearin**, of which ordinary tallow candles are made, **olein**, the chief ingredient of olive-oil, and **palmitin**. The fat of the human body consists of a mixture of these three, and is liquid at the ordinary temperature, the olein keeping the other two in solution.

The body of an average man contains about 16 per cent of fats.

Now, while it is said that a human body consists of so much water, so much salts, so much proteid material, so much carbo-hydrates, and so much fat, it is not to be supposed that these exist in a condition easily separable from one another.

Take a piece of the red flesh (muscle), it does not only contain proteids but also water, salts, carbo-hydrates, and fats. They are blended or mixed together, as it were, in the muscle, and in different cases the amount will vary. Fat exists in the muscle even though it be not visible to the naked eye; the microscope will show minute fat cells (see p. 17) between and among the muscular fibres.

It requires to be noted that, though the proteids are the principal kind of nitrogenous substances existing in the body, they are not the only ones.

The ferments concerned in digestion, the ptyalin of the saliva (see p. 143), the pepsin of the stomach juices (see p. 143), &c., are nitrogenous also. The colouring matters of the body, that of the blood and red flesh, and those of the bile are also nitrogenous substances. Moreover, as a result of the tear and wear of the body, and the consequent breaking down of the tissues that constantly goes on, a variety of substances is formed from proteids also containing nitrogen. Thus there can be extracted from ordinary red flesh, by means of water, a variety of nitrogenous substances, of which kreatin, kreatinin, sarcin, are the names of some. On this account they are called **extractives**. It is the presence of some of these that gives to flesh its peculiar flavour. Two other important substances produced from the breaking down of nitrogenous substances, and containing nitrogen, are urea and uric acid, found in the urine. Though found in the body, they are to be regarded as unavoidable rather than necessary constituents, since they are the result of tear and wear. In nerve tissues, as another example, are found substances called protagon, cerebrin, &c., supposed to result from nervous activity, which are also nitrogenous. In the same way the changes undergone by sugars, fats, &c., in the body, produce a series of substances that need not be named here. Though constantly found, they are not essential constituents of the body.

Briefly, then, we may put the matter thus, the human body is composed of thirteen elements, built up into compounds. The compounds may be grouped into the following classes—water, salts, proteids, carbo-hydrates, and fats. These five classes of compounds, existing as such in the body, are called the **proximate principles** of the body, and the proportion in which they exist is summarized in the following table:—

Percentages of Proximate Principles in the Body.

Water, ...	61·0	per cent.
Salts, or mineral matters,...	5·5	,,
Proteids, ...	18·0	,,
Carbo-hydrates, ...	0·1	,,
Fats, ...	15·4	,,
Total, ...	100·0	,,

Or we might put it thus:—

The body of a man weighing 148 pounds will contain of

Water, ...	90·0	pounds.
Salts, ...	8·3	,,
Proteids, ...	26·6	,,
Carbo-hydrates, ...	0·1	,,
Fats, ...	23·0	,,
Total, ...	148·0	,,

THE NATURE AND CHEMICAL COMPOSITION OF FOOD-STUFFS.

In the paragraphs in which we have considered the constitution of the human body, we

have really laid down the elementary conditions which all food-stuffs must fulfil if they are fitted to maintain the body in a healthy condition as a good working machine. We may now state these elementary conditions in as brief a manner as possible:

1. Food-stuffs must contain all the elements found built up into the various organs and tissues of the body, else they will not be sufficient to repair the waste going on in the body.

2. These elements are thirteen in number, chief among them being carbon, hydrogen, oxygen, and nitrogen.

3. The animal body cannot make use of these substances in their elementary form. The elements must be built up into compounds, more or less complex.

4. The elements are built up first by the agency of plants, acting under the influence of the sun's rays. The lower animals, used by man as food, consume plants, and build up the materials they contain into still more complex bodies. Then man uses both plants and animals as food, and builds up what they supply into the material, blood, bone, flesh, nerve, skin, &c., of his own body.

The Classification of Food-stuffs.—On page 536 it has been stated that all the tissues of the body, and nearly all the fluids, contain proteid substances in their composition, and that proteids, besides carbon, hydrogen, and oxygen, contain *as an essential element, nitrogen.* No food-stuff, therefore, which fails to contain nitrogen can be sufficient for repairing the tear and wear of the bodily machine. Besides, it has been pointed out (p. 530) that carbon and hydrogen yield, when burnt, enormous quantities of heat, that is to say, liberate large quantities of energy. So that food-stuffs, which consist mainly of carbon and hydrogen, and which contain no nitrogen, while quite insufficient for repairing wasted portions of the body, are most valuable for yielding to the body the energy for the performance of its work. Here, at once, we are provided with a principle of classifying the food-stuffs obtained from the vegetable and animal kingdom. Applying this principle we divide food-stuffs into

NITROGEN-CONTAINING or NITROGENOUS,	to which belong	**Proteids**	necessary for repairing tear and wear of the body.

and

CARBONACEOUS or NON-NITROGENOUS,	to which belong	**Sugars,** **Starches,** **Gums,** **Fats,**	specially valuable for the liberation of energy for work.

We must avoid the mistake, however, of supposing that nitrogenous food-stuffs are only useful for repairing tear and wear, and are always built up into the substance of the body. They contain, as we have seen, carbon and hydrogen, as well as nitrogen, and may thus be consumed in the body solely for yielding energy, without having previously been transformed into any of the living tissue of the body, muscles or bone or nerve, &c. All we assert is that muscle, bone, nerve, blood, &c., cannot be formed without them, since they only of food-stuffs contain the necessary element, nitrogen. This does not imply that they are always so built up. A quantity of proteid food may be eaten greater than is necessary to repair the tear and wear. In such a case the excess will undergo combustion in the body and will thus yield energy. Similarly we must not suppose that carbonaceous foods are used simply to yield energy, and are never built up in the body. For we have seen that the body contains a proportion of such compounds, and as they will also undergo waste they must be renewed from the food. What we do assert is that such substances yield energy in largest amount, and are the most useful forms of food material for the doing of work.

When we are reminded that the human body consists to a large extent of water, and to a small extent also of saline material or mineral substances, the necessity of these being present in food-stuffs is apparent. Thus the food-stuffs needed by man fall into the same five classes of compounds as the substances forming his body (p. 536). They are called the **proximate principles of food, or alimentary principles,** namely:

Inorganic	1. Water.		
	2. Salines or Mineral Matters.		
Organic	3. Nitrogen-containing or Nitrogenous.	Proteids	
	4. Carbonaceous or Non-nitrogenous.	Carbo-hydrates	Sugars. Starches. Gums.
		Fats	

The Fate of Various Food-stuffs in the body.—It may not be uninteresting to state a few of the reasons which have led to the general conclusions that have been indicated. A brief

consideration of the grounds of the conclusions will help to give a better appreciation of the relative value of the different foods, will supply the reasons for varying the kind of food taken under different circumstances, and will afford a more connected idea of the ultimate fate of the different foods in the body.

The Use of Water.—Regarding water not much more need be said. It undergoes no transformation in the body, we may say. But when we consider that the body loses daily about 10 ounces of water in the form of vapour given out in the breath, about 2 lbs. weight daily in the form of sweat from the skin, and from 50 to 60 ounces daily in the form of water given off from the kidneys, the need of replacing that loss is apparent. We shall see that all our food-stuffs contain a proportion of water in their composition, some of them consisting of water to the extent of three-fourths, and thus we are restoring water to the body with every bite we eat, as well as by the water we drink as such, or in beverages such as tea, coffee, &c.

The Use of Salines.—Salts of various kinds are also given off from the body in the perspiration (p. 309), in the excretion of the kidney, &c. (see p. 292), and they must be restored to the body.

The most familiar of the mineral substances we use in our food is common salt, or chloride of sodium (see p. 535). We know how wanting in pleasurable taste are most food-stuffs which are deficient in common salt, and how freely we add it to our food. There are, however, other saline substances always present in food-stuffs which are equally essential to the bodily well-being, though not required to the same amount. The process used in preserving food by pickling removes a considerable proportion of such saline substances from the food. If such preserved food forms nearly the exclusive diet for any length of time, serious effects on the health of the persons are produced. It is in such circumstances that scurvy appears among ships' crews. That this state of bad health is the result of the absence from the food of certain mineral substances is plain from the fact that if fresh vegetables, which are rich in the salines, be freely supplied, or in their absence other substances containing the salts, such as lime-juice, restoration of health results. A definite proportion, then, of saline substances in the food, seems necessary for the proper performance of the nutritive processes in the body.

The Use of Proteids.—The fate of proteids in the body was for a long time the subject of controversy. Liebig's view was that proteids were built up into the tissues of the body, into the flesh of muscle, &c.; and that when work was done it was done at the expense of the muscles, parts of which were broken down or underwent waste by the exertion, and thus proteid food was needed to repair this waste. If this were so it would imply that with increased work there would be increased waste of tissue and need for increased supplies of proteid foods, such as beef, fish, &c. It is extremely interesting to follow the steps by which the accuracy of this view was tested. Proteids, we have seen, are nitrogen-containing substances. If work is done at the expense of proteids then the nitrogenous waste of the body will be increased. Now, practically the only channel by which nitrogenous waste is expelled from the body is the kidneys, and it is expelled in the form of the nitrogenous body urea, the chief ingredient of the urine. If, then, work is done at the expense of proteids, at the expense of the tissues of the body, with increased work there will be an increased amount of urea expelled by the kidneys, and with less work there will be less urea expelled. In fact, the amount of urea expelled will depend on the amount of work done. This has been found not to be the case. Two German professors, named Fick and Wislicenus, made a direct experiment upon themselves. They ascended a mountain, 6561 feet high, and estimated the quantity of nitrogen given off as urea from the body during the period of their exertion, and they compared the quantity with the amount of urea given off from the body before the ascent began and after it was ended. In order not to cause errors by the kind of food taken, they ate no nitrogen-containing food for a whole day before the ascent, nor indeed any food of this kind till after the ascent was over, when they rested and took a liberal meal of meat, &c. The following is the result in the case of Fick:—

Before the ascent,	9·7	grains	nitrogen	per hour.
During ,,	6·3	,,	,,	,,
After ,,	6·1	,,	,,	,,
During the night,	6·9	,,	,,	,,

This shows that the work was not done at the expense of the tissues, else the quantity of nitrogen given off from the body would have increased. The fall in the quantity of nitrogen was due to the abstinence from nitrogenous food, and the increase during the night was in conse-

quence of the meal containing nitrogen taken after the ascent.

This result has been abundantly corroborated by later experiments. Thus, a set of observations was made on a watchmaker in the Physiological Laboratory of Munich, who was placed under three conditions. In one of the observations he received for a time no food and did no work, in a second he received a liberal diet and did no work, and in a third he received a liberal diet and did hard work. The quantity of nitrogen in the food given was estimated, and the quantity given off from the body was noted. If the quantity given off exceeded that of the food, it meant waste of tissues, loss of flesh, and the amount of flesh lost could be calculated from the excess of nitrogen expelled from the body. If as much nitrogen was not expelled as was given in the food, the conclusion was that the balance had been built up in the body, that is, the man had gained flesh, and the gain could also be calculated. Fat is very rich in carbon, and from the quantity of carbon given in the food, and the quantity given out as carbonic acid in the breath, it could be decided whether the body had gained or lost carbon. If the quantity given out exceeded that introduced as food, it was interpreted to mean that some of the stored-up fat of the body had been consumed and the man had lost fat. If the quantity given off were less, it meant that some had been stored as fat, and the man had gained in fat. The results were as follows:—

During the period of—

No food and no work the man lost 11 ounces of flesh and 7⅜ ounces fat,

Liberal diet, no work, the man gained no flesh, but 2¼ ounces fat,

Liberal diet, hard work, the man lost no flesh, but 2 ounces fat.

Work is, therefore, not done at the expense of the built-up tissues, but at the expense of carbonaceous compounds stored up, specially fat, but also carbo-hydrates, such as starch and sugar.

It appears, then, that a certain amount of tear and wear of the tissues goes on irrespective of what amount of work is done, and that this amount is not materially increased with increased work, even with hard work, so that if a certain quantity of proteid food is given per day, sufficient to repair the waste, all that is further needed is a quantity of energy-yielding food, such as fat, starch, and sugar, which should be varied according to the work done, that is, the energy expended.

Supposing more proteid food is given than is necessary to repair tear and wear of tissues, what happens to it? The excess undergoes direct combustion in the body without previous building up into tissue, and thus will yield energy and heat. It appears that some of the excess may even be transformed into, and stored up as, fat. For proteids consist, as we have seen (p. 536), of nitrogen with carbon, hydrogen, and oxygen. When proteid has been consumed in the body, the waste, as we have said, is urea, and the urea contains all the nitrogen that was present in the proteid, but it does not contain all the carbon or hydrogen. Two-thirds of the carbon and hydrogen do not appear with the expelled urea. It seems, then, that, in the body, when proteid is consumed or undergoes combustion, it splits up into two parts, one containing all the nitrogen and a third of the carbon and hydrogen, which is expelled as urea, and another part containing the remaining two-thirds carbon and hydrogen. If this remainder be not immediately consumed to yield heat and energy, it is surmised that it may be built up in the body and stored as a carbonaceous body, such as fat, or a carbohydrate, like glycogen (see p. 147). Thus dogs fed on lean meat may gain in weight by the laying on of fat, derived, therefore, from the proteid of the meat, since fat is not present to any extent in the diet.

It is of great importance to note further that if proteids are necessary for the repair of waste in the tissues, they are equally necessary for the building up of new tissues, as in the growing person, for the production of blood, the growth of muscle, bone, nerve, &c. So that, if an adult man needs only the quantity of proteid that will repair the wear of his tissues, which is not materially increased by his work, a child needs not only sufficient to repair the daily tear and wear, but also an added quantity for growth. *The child needs, then, a larger quantity of proteid in proportion than a full-grown person.* It is because this fact is not recognized that children are fed so largely on non-nitrogenous foods, starchy foods, such as arrow-root, corn-flour, &c. They thus fail to obtain enough nitrogen for the building up of new tissues, and are white-faced from deficient blood, have soft, flabby muscles, and weak, yielding bones.

The Use of Fats.—If experiments show that work is not done at the expense of the nitrogenous tissues of the body, they equally plainly show that it is done at the expense of fats and carbo-hydrates. The waste products of the

combustion in the body of fats, starches, and sugars are carbonic acid gas and water, just as urea is the special waste product of the combustion of proteids. While the amount of urea is not increased by work, the amount of carbonic acid gas given off from the lungs is markedly increased. In the case of the watchmaker, already referred to, while the quantity of urea expelled was the same during the day of hard work as during the day of no work, the amount of carbonic acid gas expelled increased from 14,000 grains on the day of no work to 18,000 grains on the day of hard work. Moreover, if the body be in a cold atmosphere, the amount of carbonic acid given off again markedly increases, indicating an increased combustion of fats and carbo-hydrates to yield heat for the maintenance of the warmth of the body. For a similar reason fat is one of the chief articles of consumption in the Arctic regions. During starvation the fats laid down in the body are the first to disappear. It thus becomes certain that fats are consumed in the body for the purpose of yielding energy for work, and heat for maintaining bodily warmth; and they are, above all kinds of food, best fitted for such purposes. If an amount of fat is given in excess of what is required for these purposes, it is stored up in the body as fat, waiting till called for.

The Use of Carbo-hydrates (sugars, &c.).—As has been already indicated in the paragraph on Fats, the sugars and starches introduced as food undergo combustion in the body for liberating energy and heat, but they are less useful than fats for these purposes, and the explanation of that fact is given on p. 532. These kinds of food-stuffs may be stored up in the body, if not immediately needed, in the form of animal starch or glycogen, which is manufactured and stored in the liver, as explained on p. 147. Thus Dr. Pavy showed by a series of experiments, conducted on dogs, that by a diet of starch and sugar the size of the liver was greatly increased, and that the increase in size was due to the increased quantity of glycogen produced in it from the starch and sugar. It is possible that subsequently this glycogen, before being consumed in the body, undergoes a further conversion into fat. It has been certainly proved that sugars and starches become transformed into fat in the body, and, if not immediately required, are stored up as such. Thus two observers, Gilbert and Lawes, fattened pigs on a diet rich in carbo-hydrates and found that 472 parts of fat were laid down in the body for every 100 parts of fat contained in the food. The increase in the fat could have been effected only by a transformation of the starch and sugar of the food into fat. The wax of bees is a fatty substance, and Huber showed that bees produced wax when supplied with nothing but sugar. Then the delicacy known as *pâté de foie gras* is made from the fatty livers of geese. The fatty degeneration of the liver is produced by stuffing the geese with a food rich in proteids and carbo-hydrates, and preventing exercise. The fat is, therefore, manufactured in the body from that which is not fat.

Sugars and starches, then, are consumed in the body for yielding energy and heat, while any excess is converted into glycogen or fat and stored till required.

We may represent these conclusions in the following table:—

Uses of the Various Food-stuffs in the Body.

WATER	Required by all the tissues. Daily supply needed to replace what is given off from lungs, skin, and kidneys.	
SALINES or MINERAL MATTERS	Enter into the composition of all the tissues, and promote their healthy activity.	
PROTEIDS	1. Build up tissues, muscle, bone, nerve, &c., in the growing person. 2. Repair the tear and wear of the tissues, constantly occurring, irrespective of work.	**Excess** 1. May be directly consumed to yield energy and heat. 2. Part may be stored up as fat till required. 3. Part may be stored up as glycogen.
FATS	Undergo combustion to yield (1) Energy for work, (2) Heat.	**Excess,** Stored up as fat till required.
CARBO-HYDRATES (Sugars, Starches, &c.)	Undergo combustion to yield (1) Energy for work, (2) Heat.	**Excess** Stored up as (1) fat, (2) glycogen.

The practical conclusions from these considerations have been already indicated, but will bear repetition.

There is a marked difference, in the proportion of the various kinds of food-stuffs, between the diet suitable for the full-grown person and that for the growing child.

As regards the full-grown man—

1. He needs a quantity of proteids sufficient to repair tear and wear of tissues. This quantity is, broadly speaking, the same from day to day, and is not materially affected by the amount of work done.
2. He needs a quantity of fats and carbo-hydrates, increasing (1) with increased work, in order to yield an increased amount of energy, and (2) in a cold climate or in cold weather, to yield an additional quantity of heat, and decreasing with lessened work or warmer weather.

As regards the growing person—

1. He needs a quantity of proteids sufficient to repair tear and wear of tissues.
2. He needs, over and above, a quantity of proteids for purposes of growth.
3. He needs fats and carbo-hydrates according to exercise, external cold, &c.

These facts show at once the great value of milk as a diet for children, and its much less value as a diet for adults. It contains a quantity of proteids, relatively large in proportion to the fats (cream) and carbo-hydrate (sugar of milk) it contains, and thus meets the wants of growing tissues, but the adult needs a larger proportion of the fats and carbo-hydrates, for the doing of work, than it affords.

Setting water and saline materials aside as being derived from the inorganic world, the world of lifeless matter, it will help us greatly in realizing the extent of the proteids, fats, and carbo-hydrates, derived from the organic world, if we now give a list of the most commonly known food-stuffs, indicating into which of these classes they fall.

NITROGENOUS OR PROTEID FOOD-STUFFS.

From Animal Kingdom.	From Vegetable Kingdom.
Butchers' Meat of all kinds.	Beans, Peas, Lentils.
Poultry.	Wheat, Oats.
Wild-fowl.	Flour and Oatmeal.
Game.	Rye, Barley.
Fish.	Indian Corn, Rice.
Shell-fish.	Potatoes.
Eggs.	Vegetables of all kinds.
Milk.	Fruits of all kinds.

NON-NITROGENOUS OR CARBONACEOUS FOOD-STUFFS.

Sugars.	Starches.	Fats.
Cane-sugar.	Sago.	Butter.
Grape-sugar.	Corn-flour.	Dripping.
Beet-sugar.	Arrow-root.	Lard.
Treacle.	Tapioca.	Butterine or Oleo-Margarine.
Golden Syrup.	Cassava.	Oils, such as Olive and Almond Oil, &c.
Honey.	Tois-le-mois	
Manna.		

Gums also belong to the Non-Nitrogenous class.

With the knowledge we have thus far gained, it is possible for us to make some broad general statements. Thus we can say that a diet which consisted almost exclusively of corn-flour, arrow-root, or sago would be entirely an improper diet because of its want of nitrogen, and of its consequent utter inability to yield material for building up wasted tissues. But such general knowledge as this is of very limited value. We can say that beef is nitrogenous, and is, therefore, a food-stuff that will yield the material for repairing the waste of the body. But besides nitrogenous or proteid material, beef contains other substances, and we have as yet no information that will enable us to judge how much nitrogen one pound of beef may contain, and how much of it will be necessary for a day's ration. We have as yet no means of saying whether beef or beans supplies the nitrogen in largest amount. In order to obtain this fuller information a complete analysis of the various food-stuffs is necessary. Such complete analyses have been made. They show that any one of the nitrogenous food-stuffs named in the above table is really a mixture of two or three, sometimes of all, of the classes of food material tabulated on p. 538. Thus beef is a mixture of water, mineral matters, fat, and nitrogenous material; milk is a mixture of water, saline matters, fat, carbo-hydrate in the form of sugar, and nitrogenous matter in the form of curd; oatmeal contains water, mineral matters, carbo-hydrate in the form of starch, fat, and nitrogenous material—some, that is to say, of all the different classes of food-stuffs; and so on. This is shown in a very striking way in Plate IX., where the composition of various animal and vegetable food-stuffs is represented by variously coloured bands. Each band represents 100 parts of the food-stuff, say 100 lbs., and it is divided by small marks above it into 100 equal parts. The portion of the band marked blue represents the amount of nitrogenous material in the 100 of the food-stuff. The yellow part of the band

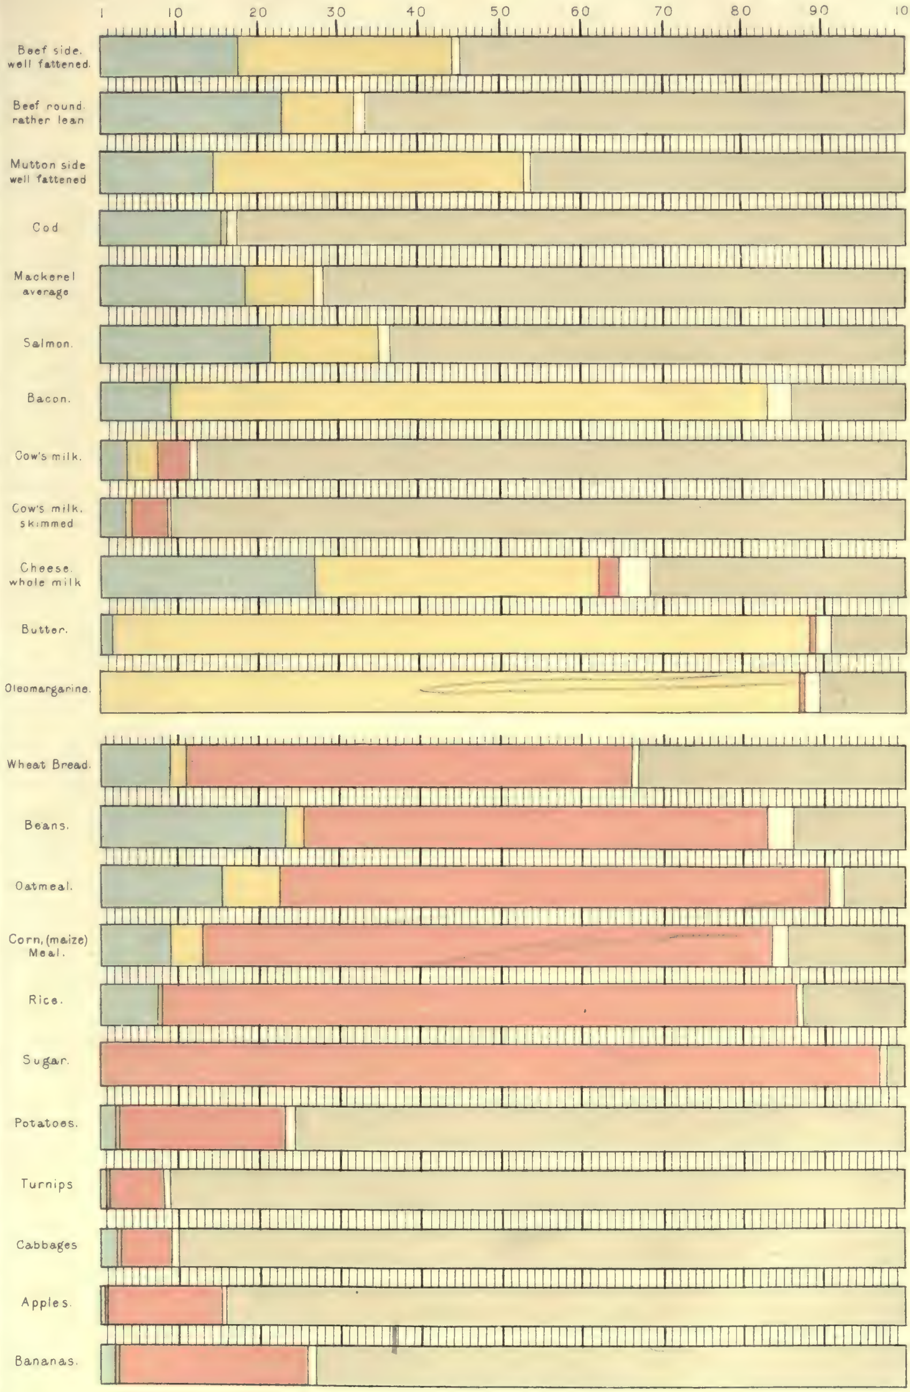
PLATE IX.—THE COMPOSITION OF FOODS.

Proteids or nitrogenous substances consist of carbon, hydrogen, oxygen, nitrogen, and sulphur. The type of proteids is white of egg. These proteid bodies are found in muscle, in nerve, in glands, in blood, and in nearly all the fluids of the body.

Carbo-hydrates are formed of carbon, hydrogen, and oxygen, the last two being in proportions to form water. Starch is a carbo-hydrate, and is found in the body in the form of animal starch. Sugar is another of this class of substances, and is found as **grape-sugar** in blood and liver, **muscle-sugar** in muscle, and **milk-sugar** in milk.

THE COMPOSITION OF FOODS.

Plate IX.



Each band represents the composition of 100 parts of the food-stuff. The fine lines between the bands are hundredths, and the fewer and darker lines are tenths. Each band is thus provided with a scale by means of which the proportion of each ingredient can be easily read off. The scale above the first band is numbered and by carrying the eye down the plate the number can be easily made to apply to the other bands also. Thus wheat-bread is seen to consist of proteids to the extent of 9 per cent. of fat to the extent of 2 per cent. of carbo-hydrates. (sugar and starch) to the extent of 55 per cent. of mineral matters 1 per cent. and of water 33 per cent. while butter contains about 1½ per cent. proteids, 87 per cent. fat, barely 1 per cent carbo-hydrates. 2 per cent. mineral matters, and rather over 8½ per cent. water.

Explanation of Signs.

Nitrogenous. or Proteids. — Fats. — Carbo-hydrates (Sugar & Starch) — Mineral Matters. — Water.

represents the fat, the red the carbo-hydrate (which may be sugar or starch, or a mixture of both), the white portion indicates the saline, and the black the amount of water. To give a complete example. Beef, from the side, well fattened, contains 17·5 per cent proteid, nearly 27 per cent fat, something over 1 per cent mineral material, and fully 54 per cent water, no carbo-hydrate.

With such analyses as these our knowledge of food-stuffs ceases to be vague and general, and questions as to the best food for building up tissues and for liberating energy can be readily answered, while we are supplied with the means of comparing various articles of food and determining their relative value.

We shall, therefore, now proceed to go over the various articles commonly used as food, giving tables of their composition. After that we shall be able to discuss fully questions relating to diets—what quantities and kinds of food ought to be used by the average person per day, and to give details as to how a diet should vary in accordance with varying circumstances of age, sex, work, and climate, &c.

COMPOSITION OF ANIMAL FOODS.

I. Nitrogenous Animal Foods.

BUTCHERS' MEAT.

Percentage Composition of Meat.[1] (Letheby.)

	Lean Beef.	Fat Beef.	Lean Mutton	Fat Mutton	Fat Pork.	Veal.
Water, ...	72	51	72	53	39	63
Nitrogenous, .	19·3	14·8	18·3	12·4	9·8	16·5
Fat, ...	3·6	29·8	4·9	31·1	48·9	15·8
Saline,..........	5·1	4·4	4·8	3·5	2·3	4·7

An examination of the above table reveals some very interesting facts. It will be noticed, first, that the proportion of water present in meat is very much higher than would ordinarily be supposed. It varies from about 50 to about 70 per cent. That is to say, 4 lbs. of lean beef, if perfectly dried, will shrink to rather less than 1¼ lbs. The second readily observed fact is that there is a relation between the quantity of water and the quantity of fat. It will be seen that when the proportion of water is large the proportion of fat is small, and when the proportion of fat becomes large the amount of water is diminished. Thus fat beef contains 21 per cent less water than lean beef, but 26 per cent more fat. Fat, that is to say, displaces water. This is quite in keeping with the popular notion that very lean beef is not economical. At the same time an excess of fat is undesirable and wasteful; for then it cannot readily be made use of, and, as the table shows, taking equal weights of lean beef and fat beef, there is less nitrogenous material in the fat than in the lean. The fat ought not to be in large masses on the meat, but should be distributed throughout it, showing as white lines running through the beef, giving it a marbled appearance. The amount of fat laid down in an animal's body is dependent upon a variety of circumstances. The kind of feeding has a marked influence, and the mode of life affects the fattening process in a very marked way. Animals in the wild state do not fatten. Fat is not laid down in the body, because carbonaceous substances are consumed in the body for yielding the energy needed in the state of unrestrained freedom. It is estimated that of the total weight of an ox ready for the market one-third is fat, and that fat forms rather more than the same amount of the body of a sheep.

There is also a considerable difference between the flesh of young and of mature animals. As a rule, while the flesh of the young animal is more tender, it is less nutritious and less digestible. Specially is it likely to be less nourishing if the animal has been quickly fed for the market. Enough time has not been given to permit the development of the muscular fibre, which is, in consequence, flabby and insipid. On the other hand if the animal has been too old or has been used for work, the flesh is too firm and hard to make pleasant eating.

Beef is said to be at its best when cut from the carcass of a four-year-old ox, and wether mutton from a three-year-old is in the best condition.

There is an important point on which the table is silent, and on which, indeed, chemical analysis can give no information, and that is flavour. It depends upon the presence in the meat of a series of bodies, which, because they can be dissolved out by water, are called **extractives** (see p. 537). They are found in greatest abundance in the flesh of wild animals, and it is their presence in more than usual quantity that gives to meat the quality people speak of as "richness." It is because the flesh of young animals is so deficient in these bodies that it is poorer and less tasty than that of the mature animal. Flavour also varies with the animal, the flesh of each kind having its own peculiar character. It is influenced by the feeding, being best just before removal from green pasturage

[1] These analyses differ considerably from those in Plate IX. The above are analyses of English samples, those of this Plate are American.

in the months of September and October; and it is diminished by artificial feeding. It is the natural feeding and the unrestrained life that give mountain-fed mutton the quality that makes it so desired. Turnip feeding imparts a particular kind of flavour.

The analyses given in the table apply to meat without the bone, and if any calculation is made, by means of the table, of the various nutritive materials present in, say 1 lb. of beef, as bought for domestic purposes in the ordinary way, due allowance must be made for the inevitable piece of bone. It has been calculated that of a whole ox carcass bone forms from 10 to 20 per cent of the whole weight, but the amount varies according to the cut.

Thus joints seldom contain less than 8 per cent of the weight in bone.
The neck and brisket contains 10 per cent do.
The shin and legs 33 to 50 per cent do.

Thus the most economical parts are the round and the thick flank, next in order comes the brisket, and lastly the leg. In mutton and pork the leg is the most economical and then the shoulders.

Bone, however, is not an innutritious portion of the animal, provided the nutriment is properly extracted from it. Church gives an analysis of the bone of a mutton chop, showing the following ingredients:—

Water	32·2	per cent or	5 oz. 66 gr. in 1 lb.
Nitrogenous	18·7	,,	2 ,, 434 ,, ,,
Fat	9·0	,,	1 ,, 193 ,, ,,
Saline {Phosphate and carbonate of lime}	40·1	,,	6 ,, 182 ,, ,,
	100·0		16 oz.

Smith, basing his calculation upon the analysis of shin-bones, estimated that

3 lbs. of shin-bones would yield as much carbon as 1 lb. of beef.
6 lbs. of shin-bones would yield as much nitrogen as 1 lb. do.

that is, the nutritive value of bone is as regards nitrogen $\frac{1}{6}$ that of beef, and as regards carbon $\frac{1}{3}$ that of beef. Bones vary in the amount of nutritive material they contain according to their form. Dense bone contains less animal and more mineral matter than spongy bone, and the more abundant the marrow the more useful the bone, for marrow consists largely of fat, and is therefore of value as yielding carbon for liberation of heat and energy. In order that the nutritive material may be properly extracted bones require grinding down. This could not be attempted for ordinary domestic purposes, but at any rate the bone ought to be well smashed up, to permit the extraction of as much nutriment as possible. The joint ends of bone yield, from the gristly material and from the tendinous and ligamentous parts about the joint, a substance which, on boiling, is converted into gelatine. It is this, perhaps, more than the nutritive material extracted from the bone itself, that makes the bone useful for the making of stock for soup.

Percentage Composition of Various Parts of Animals.

	Sheeps' Kidney.	Calves' Liver.	Tripe.	Foie Gras.	Bacon, fat salted and dried.
Water	78·60	72·33	67·1	22·70	13·9
Nitrogenous,	16·56	20·0	13·3	13·75	9·0
Fat	3·33	5.58	17·1	54·57	74·1
Carbo-hydrate.	0·21	0·45	—	6·40	—
Saline	1·30	1·54	2·5	2·58	3·0

The above tables show the nutritive value of the various internal organs noted. There are, however, objections to their use, mainly on account of their being difficult of digestion. Thus the kidney is of a close texture, and unless skilfully cooked, so that all the juices are retained, it may be hard and with little flavour. The same objection exists to the use of the heart, which closely resembles ordinary meat in its composition, though it is much firmer and harder. The liver is rich and savoury when properly cooked, but easily rendered hard and tasteless, and is difficult of digestion. Comparison between the table of calves' liver and foie gras, the fatty liver of Strasburg geese (see p. 541), indicates how the kind of feeding followed in the case of the geese alters the composition of the organ. The table shows the fatty liver to consist of over a half of fat. Tripe used as food consists of the paunch, or first portion of the stomach of the ox or cow. Of considerable nutritive value, it possesses the great additional advantage of being the most easily digested of animal foods, and it is of very agreeable flavour. Sweetbread is, strictly speaking, the pancreas (see p. 142), but the organ sold by butchers under this name is specially the thymus gland (p. 205), and other glands, such as the thyroid (p. 205), are also sold under the same name. The thymus of the calf is the most esteemed. It is nourishing, and when properly cooked easy of digestion. The lungs or lights are eaten along with the liver, and

though containing nutritious material are rather indigestible.

The blood of animals, chiefly the pig, is consumed in the form of black-puddings, which are made of a mixture of blood, groats, fat, and various herbs. The mixture is contained in a piece of skin from the intestine of the pig. Bacon belongs to the class of cured meats. The flitch is from the side. The process of curing consists in rubbing into the side a mixture of salt and saltpetre (nitre). Brine is also forced into the flesh by a force-pump. The sides, after being dressed in this way, are piled on one another for four days, then turned and sprinkled with salt, and allowed to lie for twelve days. After washing and drying they are hung in the smoke-house and submitted to the fumes of burning oak sawdust for three days, when they acquire the proper flavour and are ready for market. "For domestic use pork may be cured as follows: Stir some salt with hot water till no more of the substance is dissolved. This forms the brine or pickling liquor. Then mix, for a pig of moderate size, one pound of brown sugar and half a pound of nitre; rub this mixture well into the meat, which is then to be put into the pickle, remaining there two days. After this take it out and rub the pieces with salt alone. Return it to the pickle. It will be ready for use, after drying and smoking, in six or eight weeks" (Church). The small quantity of water contained in bacon makes it, weight for weight, of more nutritive value than fresh pork, while the pickling process renders the fat more digestible than it is in the fresh state. This is an exception to the general rule that curing renders meat less digestible. If the pickling has been too long continued, however, the lean portions will have become too dry by the abstraction of the juices. By noting in the above table the relative proportions of nitrogenous material and fat in liver and bacon, the meaning and advantage of combining these two in one dish becomes apparent, the one making up for the deficiencies of the other. The same is true of the combination of chicken and ham, for the flesh of fowls, as will be seen from the succeeding table, contains a very slight admixture of fat, while it is more than usually rich in nitrogenous material.

The same advantage is gained from a mixed diet of ham and eggs, veal and ham, bacon and beans, rabbit and ham, &c., the bacon or ham supplying in each case the fat, while the eggs, beans, veal, or rabbit yields in abundance the nitrogenous constituent.

POULTRY, GAME, AND WILD-FOWL.

Percentage Composition of Poultry and Game.

	Fowl.	Hare.
Water	73·15	74·35
Nitrogenous	22·65	23·34
Fat	3·11	1·13
Saline	1·09	1·18

The number of birds used as food, in various parts of the world, is very great. The analysis of the common barn-yard fowl may be taken as a fair sample. It will be noticed that the proportion of fat is small, and the proportion of nitrogenous material large, the latter existing in larger quantity even than in lean beef. Wild-fowl contain still less fat. The flesh of the white-fleshed birds is more tender, more delicate in flavour, and more easily digested than the dark-coloured flesh, for example, of ducks and geese. The latter is, however, richer and more stimulating. Game-birds are desired for their special flavour, which, by stimulating the appetite, counterbalances the disadvantage of the increased firmness and solidity of the flesh. The character of the flesh is, of course, influenced by domestication. If prevented from obtaining exercise, the birds will become fat, and it also appears that, after spaying, the animal fattens more easily, grows to a larger size, and develops a finer flavour. A *capon* is a cock-chicken which has been thus treated, a *poulard* is a spayed hen. The flavour is also markedly different in flesh-eating from that of grain-eating birds. The flesh-eating bird is of a stronger, fuller, and less agreeable flavour, and the feeding of such birds on grain greatly improves them in this respect. The keeping of game, till it is decidedly "high," is for the purpose of making the flesh more tender and easily eaten.

The breast is not always the most tender part of the bird. It is so in the common fowl and the partridge, because these birds walk rather than fly, and the wings and breast muscles are less exercised. But, in the case of the woodcock and snipe, the legs are preferred, because these birds fly most, and the wings consequently are firmer from exercise.

While there seems to be no bird whose flesh is injurious, if eaten, it yet appears that some birds may become poisonous by eating certain foods. The pheasant of North America is said to be poisonous during the winter and spring, if fed on the buds of *Calmia latifolia*, and American partridges have been found to possess poisonous properties (Pavy).

The flesh of hare and rabbit resembles that of fowl rather than that of butchers' meat. It also is characterized by the absence of fat. The flesh of the hare is particularly rich and nourishing, that of rabbit having a less defined flavour; but it is more easily digested, and, just because of its greater delicacy, is more suited for an invalid or convalescent. Hare-flesh is highly nutritious, but is rather for the healthy and vigorous than for the sick.

Venison, the flesh of the deer, resembles game rather than butchers' meat. It possesses little fat, but is rich in extractives, and therefore savoury and stimulating. It is, moreover, readily digestible. The flesh of park-deer resembles that of the domestic sheep because of restricted exercise.

Squirrels are eaten in some of the western parts of America, and by the natives of Australia, and form a favourite dish in Norway and Sweden. The flesh is said to be tender, and to resemble that of the barn-door fowl. The flesh of the opossum is compared to that of the rabbit or hare.

Edible birds' nests are esteemed great delicacies in China. The edible portion of the nest is really formed of dried saliva, and is constructed by the bird, the salangan, a kind of swift, as a support on which its nest is afterwards raised of grass, leaves, and sea-weed. The birds build in caves near the sea or inland, and it is by means of the brackets which the animal makes, that its nest is supported. It is said to require fifty such brackets to make up a pound in weight, and the best of them sell for £5 to £6 the pound. They are obtained chiefly in the islands of the Southern Archipelago.

EGGS.

Percentage Composition of Hen's Egg (*Church*).

	White.	Yolk.	White and Yolk Mixed.
Water	84·8	51·5	71·7
Nitrogenous	12·0	15·0	14·0
Fat	—	30·0	11·0
Extractives and membranes	2·0	2·1	2·0
Saline	1·2	1·4	1·3

The eggs of a great variety of birds are used as food, and there is no bird's egg which may not be so employed. The eggs of different birds differ much not only in size, &c., but also in flavour. The flavour is mainly determined by the feeding of the bird.

Within the shell the whole egg is inclosed in a delicate double envelope or membrane. Throughout the white of the egg run delicate strands of membrane dividing off compartments in which the semi-liquid white is inclosed. Within the white, inclosed also in a delicate membrane, is the yellow yolk attached to the membranes of the white by two fine cords or chalazæ, one towards each end of the egg, which suspend the yolk and permit it to move readily within the white. It is on the yolk and from a part of it that the young bird is developed. The part is indicated in the fresh egg by a small white area, called the cicatricula, about the sixth of an inch in diameter, which is always uppermost in whatever position the egg is placed. The rotation of the yolk on its chalazæ achieves this. While only a part of the yolk developes into the young bird, the remainder and the whole of the white serves to nourish it till it is ready to break out of the shell. So that within the egg itself is contained all the material necessary for the development of the tissues and growth of the chicken during a considerable period of its existence.

The shell is usually about the $\frac{1}{10}$th of the total weight of the egg, the yolk weighs $\frac{3}{10}$ths, and the white $\frac{6}{10}$ths.

The shell consists of 3 per cent organic matter, and 97 per cent inorganic salts, of which 91 per cent is carbonate of lime, and the remaining 6 per cent is phosphate of lime. It is porous, and thus permits exchanges to go on between the air outside and the contents of the shell. It is because of the entrance, through the shell, of putrefactive germs in the air that decomposition is set up, and the egg becomes bad. This may be prevented by rubbing newly-laid eggs over with fat or butter, which enters the pores and seals the egg, as it were, against the entrance of air. Eggs have been kept fresh for two years, and may easily be kept, it is said, by covering them with a solution of one-third bees'-wax and two-thirds olive-oil. They may be kept for a considerable time also by packing them, small end downwards, in clean dry salt. They may be preserved also in strong solution of salt or in lime-water. Bad eggs swim even in pure water because of their loss of weight owing to decomposition, and the quantity of gas the decay has produced. Good eggs should sink in a solution composed of 1 ounce of salt in 10 ounces ($\frac{1}{2}$ pint) water, and in the same solution indifferent eggs float. The white and yolk of eggs differ very much in their composition, as the tables show. The white is almost entirely a weak solution of albumin in water, for the nitrogenous constituent is pure albumin (see

p. 536), and the water exists to the extent of nearly 85 per cent. So that of the white of egg only ⅛th part consists of really nourishing material, namely, the albumin. Though in solution in cold water, it becomes coagulated into a white clot when heat is applied, and the albumin in this coagulated condition will no longer dissolve in water. When the composition of the yolk is examined, a marked difference is observed. There is 33 per cent less water, and 30 per cent fat, besides 3 per cent more albuminous or nitrogenous material. The fat may be extracted as a bright yellow oil by means of alcohol or ether. The yolk is much richer then, and more nourishing than the white. Yet the white forms $\frac{6}{10}$ths of the whole egg, so that when the mixed white and yolk are taken, the rich yolk is diluted, as it were, by the weak white, as will be seen on referring to the table. It is sufficiently plain from these tables that eggs are not the concentrated food most people imagine. As a matter of fact an egg scarcely contains more nourishing material than a piece of beef of equal weight. This is proved in more detail on p. 555. A man, restricting himself to eggs alone, could not obtain sufficient waste-repairing and energy-yielding material out of less than eighteen eggs per day.

The inorganic salts of the egg are those of phosphorus, iron, lime, soda, potash, and magnesia.

The weight of the hen's egg is from 1½ to 2 ounces; a duck's egg weighs 2 to 3 ounces, a turkey's 3 to 4 ounces, and that of a goose 4 to 6 ounces. A duck's egg contains a fourth more nourishing material than a hen's egg.

FISH AND SHELL-FISH.

Percentage Composition of White Fish.

	Whiting.	Cod.	Haddock.	Sole.	Skate.
Water........	83·0	77·5	78·0	86·1	73·79
Nitrogenous	15·1	18·5	18·1	12·0	24·03
Fat............	0·8	3·0	2·9	0·7	0·47
Saline.........	1·1	1·0	1·0	1·2	1·71

Percentage Composition of Fat Fish.

	Herring.	Mackerel.	Eel.	Salmon.
Water............	80·71	68·27	79·91	74·45
Nitrogenous....	10·11	23·42	13·57	18·75
Fat..................	7·11	6·76	5·41	6·22
Saline	2·07	1·55	1·11	0·58

In the above tables a rough distinction has been made between two classes of fish, depending on their chemical composition. To the class of lean fish, that is, with comparatively little fat in their composition, belong the fish with more or less white flesh. The commoner examples of this class are given in the table, and to the same class, with a chemical composition of which that of the haddock may be taken as an average, belong turbot, brill, plaice, whitebait, smelt, flounder, hake, ling, gudgeon, and pike. The class to which herring, salmon, &c., belong is characterized by a considerable increase in the quantity of fat, and has usually flesh more or less coloured. The sprat, pilchard, and lamprey belong to the same class. According to the table the herring is richest in fat; but the eel is usually represented as one of the fattest of fish, Letheby's analysis crediting it with nearly 14 per cent of fat, and Payen stating the percentage of fat in the eel, when the non-edible parts have been removed, as nearly 24. It may be remarked here that there are considerable variations in the analyses of different food-stuffs, as given by different authorities, depending upon the state of the particular samples from which the analyses were made. Thus in fish the composition varies with the season, the animal being at its highest state of perfection previous to spawning, when it is fatter, and the flesh has a richer flavour. After spawning the animal is much leaner and the flesh is more watery. It is estimated that during the spawning period as much as 17 per cent of the total fat present in the body may disappear.

In the case of the salmon, herring, mackerel, eel, &c., the fat exists among the muscular substance, and there is also a layer of fat beneath the skin, specially beneath the skin of the belly, whereas, in the cod, skate, &c., the fat is present in greatest amount in the liver, which is, in the season, gorged with oil.

Fish compares favourably with butchers' meat, containing a nearly equal amount of nourishing material, weight for weight, as beef. The extractives, to which butchers' meat owes its richness and fulness of flavour as well as its stimulating properties, are present in less quantity, however. Fish is thus less satisfying and stimulating than beef, and is, on that account, not so extensively used as it ought to be. Because of this, however, its nutritive value is not actually impaired, while these qualities make it of much value to persons of weak digestion and to persons of sedentary habits. Its deficiency, specially the deficiency of white-fish, in fat is easily made up by mixing the diet with fatty substances. Butter sauces, for example, make up for this. Fishing populations

have learned this by experience. Thus the people of Cornwall and Devonshire make a fish-pie of fish mixed with thick pieces of fat pork, salted and peppered,and covered by a good crust. They thus obtain all the requisites of a nourishing meal; and the healthy condition of the people shows how satisfactory is the diet. "In no other class than in that of fishers do we see larger families, handsomer women, or more robust and active men" (Dr. Davy). The value of fish from an economic point of view, as compared with butchers' meat, is discussed on p. 555.

The flavour of fish varies with their feeding, the special character of the feeding-ground being the cause of the peculiar excellence of Loch Fyne herring, Dublin Bay haddock, Dogger Bank cod, and Tay salmon. The whiting is the most delicate and tender, and near it is the haddock; the sole, flounder, turbot, cod, hake, and ling follow. The white-fish are the most digestible; and diminished digestibility accompanies increased firmness of flesh. This is seen in cod-fish, which in season is firm, and becomes opaque on boiling, showing curdy material between the flakes. But this very firmness, desirable as indicating seasonableness, is a disadvantage from the point of view of digestion. The firmness of the cod is increased by crimping, which consists in making cross-cuts into the flesh immediately after the fish is killed, and then plunging it into cold water. This is supposed to improve the flavour. The flavour of some fish, such as trout and salmon, is best when they are cooked and eaten speedily after being killed; but others, such as turbot, improve with keeping. The fat fishes are the least digestible of all.

Roe and milt are parts of the reproductive organs, the former, which is the hard roe, belonging to the female, and the latter, the soft roe, to the male. Caviare is the preserved hard roe of the sturgeon.

Many substances of great commercial value are made from various parts of fish. Thus isinglass is derived from the swimming-bladder, specially of the sturgeon. Glue is made from refuse of fish; and so on. The Normal Company, of Aberdeen, has shown that every part of the fish can be utilized, and that the parts of the fish regularly discarded as useless, when properly made use of, represent an enormous money value.

Fish sometimes possess poisonous properties, possibly because of some kind of feeding. Such poisonous fish are met with in the tropics. There are some people injuriously affected by fish at any time, even as others cannot eat mutton or eggs without great disturbance.

There does not seem any scientific ground for the popular notion that fish is a specially useful food for brain workers. It was thought that fish were rich in phosphorus, which enters into the composition of brain tissue, and were, therefore, specially useful. This idea arose from the glow given out by fish in the dark. But such phosphorescence is probably due to a minute organism, and is a thing apart from the chemical composition of the fish.

Percentage Composition of Shell-Fish.

	Lobster.	Oysters.	Mussels.
Water,	76·62	80·38	75·74
Nitrogenous,	19·17	14·01	11·72
Non-nitrogenous and loss,	1·22	1·40	7·39
Fat,	1·17	1·52	2·42
Saline,	1·82	2·69	2·73

The above may be taken as fairly representative of the shell-fish class. They contain a fair quantity of nourishing material. In the case of lobster, crab, crayfish, &c., there are serious objections to their use. They are among the most indigestible kinds of animal food. They are coarse feeders, and this may account for the disturbing effects they so readily produce, apart altogether from any difficulty of digestion. Under any circumstances, however, they excite even serious irritation of stomach and bowels in some persons, producing cramp, colic, purging, and violent symptoms of irritant poisoning; while in others the partaking of even a small amount of shell-fish (and specially mussels) to supper would induce a skin eruption like nettle-rash. Oysters are not so open to this objection; indeed they are frequently found pleasant and appetizing by persons of weak digestion and convalescents. The flesh of the claws of lobsters and crabs is more delicate and digestible than the soft internal parts, which are mainly liver. The mass of little round black bodies, found beneath the tail of the female lobster, is the spawn, and is used for sauce. The beard of the oyster is formed of the gills, and is frequently removed; the large hard portion of the interior, which is a muscular part, ought also to be rejected, as it is the least digestible part. The addition of vinegar, spices, &c., to shell-fish is, as a rule, an aid to their digestion, as these substances act as stimulants to the stomach and promote the flow of the digestive juices. Oysters are more easily digested when raw than when cooked. They are in season only when there is an "r" in the name of the month.

TURTLE.

Both the fresh-water and marine turtle are consumed as food. The former abounds in certain districts of the Continent, and is used by the inhabitants. The *terrapin*, a fresh-water turtle, is imported into this country from America. Land tortoises are also found wholesome and agreeable food by the natives in India and Africa and by the North American Indians.

The edible or green turtle (*Chelonia mydas*) is the one chiefly used in this country. It is from 6 to 7 feet long, and sometimes weighs 700 pounds. They are imported alive; and the flesh cut up into pieces and sun-dried is also imported in large quantity from the West Indian islands. The flesh is sometimes used as steak, but is principally employed for soup. For this purpose the shields covering back and belly are removed from the animal, scalded to allow of the removal of the scales, and boiled. The soft, glutinous parts are then removed from the hard bony portion and cut up into small oblong pieces. It is these pieces that are prized, and are erroneously called green fat. The liquor is used as stock for soup. The shield from the back is called callipash (the carapace of naturalists) and that from the belly callipee—names well known to cooks, epicures, and aldermen. "The callipee, or underpart of the breast or belly, baked, is reckoned the best piece." It is white, like veal or chicken, after being boiled. The meat from the callipash is dark-coloured, and is sometimes called black or green meat. The fat of the turtle is greenish-yellow in colour, and it also is used for soup. It is said to colour the urine and sweat of those who eat of it. Turtle is said to be highly nutritious, and when plainly cooked easy of digestion—tender, delicate food when young, but more tough and gristly as it grows old. "The juices are generally reckoned great restoratives."

The eggs of the turtle are also used as food. They are deposited in great numbers in the sand of the bays and lagoons, to which the turtle resorts for that purpose several times a-year. They are hatched lying in the warm sand, and the difficulty is to procure them in a perfectly fresh state.

The flesh of the turtle is about 75 per cent water, and of the remaining 25 per cent about one-half is fat, the rest being flesh.

Mock-turtle soup is made with pieces of the gelatinous portions of the scalp of the calf's head, which resemble to some extent the glutinous pieces of turtle.

MILK.

Average Percentage Composition of Human Milk and Milk of Different Animals.

	Human	Cow.	Ass.	Goat.	Mare.	Sheep.
Water,.........	88·0	86·87	91·17	87·54	88·80	82·27
Nitrogenous,.	2·97	4·65	1·79	3·62	2·61	7·10
Fat (Butter),.	2·90	3·50	1·02	4·20	2·50	5·30
Sugar,..........	5·97	4·28	5·60	4·08	5·59	4·33
Saline,..........	0·16	0·70	0·42	0·56	0·50	1·00

Milk is an emulsion. It consists, when seen under the microscope, of a multitude of exceedingly fine globules of oil, each globule being surrounded by an albuminous film, which keeps the globules from running together, the globules floating in an opaque fluid. The fluid contains albuminous bodies, milk-sugar, and salts, in solution. When perfectly fresh it is slightly alkaline in reaction, but it soon becomes somewhat acid.

When milk is allowed to stand the oil-globules, being light, rise to the surface and form the layer of cream, so that the cream is mainly the fatty portion of the milk, the globules in it being still separated from one another by the albuminous envelopes. When milk is churned, the albuminous envelopes are ruptured, and the released globules of oil run together, forming little masses of fat. These masses are collected, as much of the liquid squeezed out as possible, and thus the butter is obtained. If a small quantity of acid, say common vinegar, be added to milk and the milk be slightly warmed, it separates into curd and whey. The same thing occurs if the milk is allowed to stand till it becomes sour. The souring is due to the formation in the milk of an acid—lactic acid. The lactic acid is produced by a species of fermentation from the sugar present in solution in the milk. The agent in exciting this fermentation is a minute organism (see p. 389) deposited in the milk from the air. If milk be heated, and corked in a bottle when hot, it will not turn sour, because the heating has destroyed the organism; and no lactic acid being produced, curdling will not occur. But if the cork be removed and the air have access to the milk again, fresh organisms are deposited and curdling will soon take place. The explanation of curdling is this: the chief nitrogenous or albuminous body in milk is called casein. Casein belongs to the same type of substances as white of egg. We all know that white of egg will dissolve in cold water, but as soon as the water is heated to the boiling point it separates or is precipitated as a white curdy mass. Now while

casein of milk is akin to white of egg, unlike it, it does not precipitate on boiling, so long as the solution, in which it is present, is not acid but alkaline. As soon as the solution becomes acid, either by the addition of a little vinegar, or by the process of souring, the casein tends to become precipitated as curd, and will be all the more quickly precipitated if the solution is heated. So long as milk is kept alkaline, then, it will not curdle, because casein is soluble in an alkaline solution, and is therefore called alkali albuminate. The addition, therefore, to milk of a little common baking-soda (carbonate of soda) will prevent curdling taking place. Milk is also separated into curd and whey by mixing it with rennet. Rennet is prepared from the stomach of the calf, and contains a special ferment, which causes the precipitation of the casein. In the process of the digestion of milk in the stomach curdling is the first step, being caused by the acidity of the gastric juice, as well as by the presence in the juice of a curdling ferment. If a person vomits some time after a drink of milk, the milk is returned in a curdled condition, because the process of digestion has begun.

The curd of milk thus consists of an albuminous body casein, and entangled in the curd is the most of the milk-fat. The whey also contains some of the fat globules, and is, therefore, somewhat opaque. It contains also a small quantity of albumin of exactly the same character as white of egg, and it contains in solution the sugar, salts, &c., which can be readily separated out. If the whey be gradually evaporated the milk-sugar will crystallize out.

Milk, then, is really a very complex substance, and it contains a proportion of all the different kinds of material needed as food—nitrogenous, fatty, sugary, saline.

We must now look at its composition a little more in detail. It will be observed from the table that the composition of milk varies very much in different animals, that of the ass containing a total of only 8·83 parts of solid material in 100, while that of the sheep contains double the amount of nourishing material, namely 17·73 parts in the 100; and while

human milk contains 12 parts of solids in 100,
cow's milk „ 13·13 „ „

Solids in One Pint of Milk.

Nitrogenous, ...	369 grains.
Butter, ...	351 „
Sugar, ...	468 „
Saline, ...	72 „
Total Solids, ...	1260 grains.
Or fully	2·8 ounces.
Water, ...	17·9 „

Of one pint of cow's milk (20 ounces) 17½ ounces in round numbers are water, and 2½ ounces solid nutriment. If a grown person, therefore, were to live on milk entirely, a very large quantity would be necessary—between 9 and 10 pints daily at least. This would be an expensive diet. It is one, moreover, not suited as an exclusive diet for an adult, while eminently suited for a young growing person (see p. 542).

The nitrogenous ingredients in milk are principally the two already named—egg-albumin and alkali albuminate or casein, the casein being in largest proportion, forming nearly 4 of the 4·65 per cent.

Milk-fat or butter or cream is that which gives the quality and richness to the milk. It is by the amount of cream present that the quality of the milk is commonly estimated. There is a simple instrument, called a creamometer, which might readily be employed in households for determining the richness of milk. It consists of a test-tube (fig. 192) 11 inches long and ½ inch in diameter, which is divided into 100 degrees by a scale. The milk to be tested is well shaken to mix the cream uniformly and then the test-tube is filled with it up to the mark 0. The tube is allowed to stand upright for 24 hours, and the depth of the layer of cream on the top read off at the end of that time. Good sweet milk should give a layer of cream not less than 11½ degrees. This is, however, not a very reliable gauge, because the amount of cream which rises depends on many conditions. More cream will rise if the temperature is low, if the vessel which contains the milk is wide, and if the vessel is kept perfectly free from agitation. Another method of determining the quality of milk, which gives results varying according to whether the cream has been removed or not, is the method by taking the specific gravity of the milk. A hydrometer is used, such as is shown in fig. 193, which should sink in pure water to the level of the mark 0, which stands for 1000. In pure sweet milk it should rise to a level between 29 and 33 (1029 and 1033). That is to say, the specific

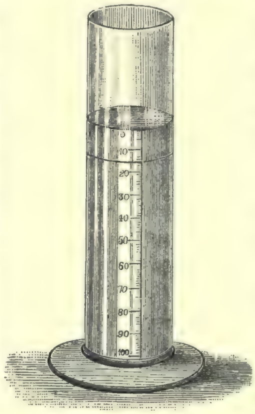


Fig. 192.—Creamometer.

gravity of pure milk varies between 1029 and 1033. Now such milk contains say about 12 per cent of cream, and if from a sample of pure milk any quantity of cream has been skimmed, the reading from the hydrometer will be considerably different. Cream, consisting as it does mainly of fat, is lighter than water. If, therefore, a large quantity of cream be present in a sample of milk, its specific gravity will be lowered; and if the cream be skimmed off, the specific gravity of the milk will be raised. Thus pure milk with all its cream, which gives a specific gravity of between 1029 and 1033, will, if the cream be removed, give a specific gravity of between 1033 and 1037. If we take these two levels as the standards of pure sweet milk and pure skimmed milk, it is plain that the addition of water to either will cause a lowering of the specific gravity. A table has been constructed, showing the fall for varying quantities of water, and thus, by using the hydrometer, with this table a rough estimate of adulteration of the milk with water might be made.

Fig. 193. Hydrometer.

Table Showing Specific Gravity of Milk before and after Removal of Cream with Different Quantities of Added Water.

Specific Gravity before Removal of Cream.	Specific Gravity after Removal of Cream.	
1029 to 1033	1034 to 1037	Indicates Pure Milk.
1026 ,, 1029	1029 ,, 1034	= 10 p.c. added water.
1023 ,, 1026	1026 ,, 1029	,, 20 ,, ,,
1020 ,, 1023	1023 ,, 1026	,, 30 ,, ,,
1017 ,, 1020	1020 ,, 1023	,, 40 ,, ,,
1014 ,, 1017	1016 ,, 1020	,, 50 ,, ,,

Hydrometers are graduated for use with milk only, and are then termed **lactometers.** Different makers graduate the lactometers in different ways. Thus one is made graduated from 100, low down on the stem, to 0 at the top of the stem. In pure water it would sink to 0, in pure milk the stem would stand out above the milk to the level 100. If it sank so that the stem stood out to the level 90 only, that would indicate that, in 100 parts, only 90 were pure milk and 10 were added water, and so on. The graduation might begin low down at 0, at which level the lactometer should stand in pure milk, and from that point up the stem the marks would indicate percentages of added water. Thus if the instrument sank to 5, that would mean 5 per cent added water. If this method of testing the quality of milk were used, and it would be of easy domestic application, it should be employed in conjunction with the creamometer, else mistakes would arise. Take an example: a fraudulent milkman might remove a portion of cream from his milk, and in consequence the specific gravity would rise, say to 1034, indicating skimmed milk. He might then bring the specific gravity back to what it ought to be for pure milk by adding water. Of course the milk would look thin, but still the specific-gravity test alone would not indicate anything wrong. If, however, the creamometer test were applied, and a marked deficiency in cream shown, the explanation would be evident. For purposes of such testing the milk should be well mixed before the sample is poured out.

The sugar of milk or lactose contains the same proportions of carbon, hydrogen and oxygen as cane-sugar, but is of feebler sweetening power, and does not readily undergo the alcoholic fermentation, but is prone to the lactic acid fermentation, which, as already stated, is the cause of the souring of milk.

The **saline constituents** consist of salts of soda, potash, lime, magnesia; oxide of iron, and compounds of phosphorus and chlorine are also present. Milk also contains fluorine, which is an ingredient in teeth. Of the total mineral constituents phosphoric acid forms no less than about 28·5 per cent.

The composition of milk varies much with the feeding of the animal. If an abundance of suitable food be allowed to the cow, and exercise be denied, the yield is increased, and the quantity of solids in the milk is also increased. Stall-fed cattle yield more butter, because less fat is consumed in the body for yielding energy for exercise and the maintenance of temperature.

The flavour of the milk is also influenced by the feeding, the finest being yielded by feeding on fresh country pasture. Turnips and fragrant grasses impart an odour to the milk. Milk also may be coloured by food eaten, and may acquire poisonous properties, without the animal being affected, by the cow, goat, &c., feeding on certain plants. This is noticed in Malta and some districts of North America.

The milk of a cow varies also at different times of the day, and the milk obtained at one milking is not all of the same richness. The afternoon milk is said to be twice as rich in butter as the morning milk. If, as a cow is being milked, the milk is divided into several portions as it comes from the udder, the milk that came first is found to vary very much from

that yielded by the stripping of the udder. The chief difference is in the quantity of butter, the first milk, or as it is called the "fore" milk, being very poor in fat, while the last milk, or the "strippings," is rich in fat. Any one, therefore, who wishes to see a fair sample of milk yielded by a particular cow should see the cow completely milked. The whole milk should be collected in one vessel, and a sample of that taken. The cause of the difference is found in the lightness of the cream, which makes it rise to the highest part of the gland.

The average quantity of milk yielded by the cow varies with the breed. The Yorkshire shorthorn, the favourite of London dairymen, is estimated to yield on a yearly average nearly a gallon and three quarters per day (strictly 1·7 gallons per day). A good average yield is said to be 15 pints per day, but, as already stated, it varies with the feeding, exercise, &c., not to speak of the condition of the animal. The udder of the cow is estimated to be able to contain about 5 pints of milk at one time.

As an agent in the communication of disease milk must not be ignored. It is perfectly certain that milk is continually the agent in spreading typhoid fever. Probably, indeed with certainty, this arises from water tainted with excretions from a patient suffering from typhoid fever, gaining access to the milk. A very common story is that some farm hand takes ill with what is called a feverish cold or gastric fever, and is ill for some weeks. The discharges are, without any precaution, cast on the dung-heap, and fluid from it finds its way into the burn or well, from which the household obtains water. This water is used to wash the milk-vessels, not to say to add to the milk, and is then conveyed to a neighbouring town or village. Germs from the patient have thus gained entrance to the milk, where they multiply, and if the milk be used unboiled, it may convey the disease to whomsoever partakes of it. In recent years it has also become almost certain that the milk of a diseased cow may occasion disease in persons partaking of it. An outbreak of scarlet fever in Hendon, in England, and another in Glasgow, were almost conclusively traced to the use of milk, yielded by cows suffering from a febrile disease, and it has become highly probable that the scarlet fever of the human subject has its counterpart in the cow, and that it may pass from the cow to the human being by the medium of the milk. Another disease that numerous investigations have shown to be probably communicable from the cow to man by the medium of milk is tubercle, the chief if not only cause of consumption of the lungs (see p. 277). It is becoming more and more certain that specifically tainted milk is constantly sold in large towns, and the question for each one to ask is, how protection against it is to be secured. It has been shown that milk containing infection may evidence to chemical analysis no change whatever, and there is really no test of quality, taste, flavour, &c., which is of any value on this question. If the milk consumer wishes any guarantee of protection, the only one of real use he can himself supply *by bringing to the boiling point, and keeping boiling for one or two minutes, every drop of milk that enters his house*, the vessel into which it is poured from the pot being previously scalded. That is to say, to be thorough, the milk is not to be poured from the pot back into the vessel, which held it at first, unless every particle of unboiled milk has been removed from the vessel by boiling water. **Human milk** varies with feeding, &c., much as cow's milk does, and is altered by disease. Medicines administered to a nursing mother may affect the child, and, therefore, caution in giving such drugs, as mercury, opium, laudanum, &c., to a nurse is necessary. Human milk, as shown by the table, contains less nitrogenous and fatty material than cow's milk and more water and sugar. To bring cow's milk more nearly to the composition of human milk, the addition of water and sugar is necessary. The following quantities are advised:—

20 ounces (1 imperial pint) cow's milk,
10 ounces (½ ,, ,,) boiling water,
1½ ounces sugar (preferably milk-sugar),
Mix.

It is said that cow's milk coagulates in larger curds than human milk, and that this accounts for the greater difficulty infants experience in digesting cow's milk. This is remedied by boiling, which causes curdling to occur in more flaky masses.

Percentage Composition of Cream, Skim-milk, Butter-milk.

	Cream.	Skim-milk	Butter-milk.	Devonshire Clotted Cream.
Water, ...	55	89	90·62	28·68
Nitrogenous, ...	6	4·3	3·78	4·05
Butter, ...	36·3	0·4	1·25	65·01
Sugar, ...	2·5	5·5	3·70	1·77
Saline, ...	0.2	0·8	0·65	0·49

Cream.—The composition of cream varies very considerably, the quantity of fat varying as much as between 12 and 50 per cent, and

the water in like proportion. Much depends upon the method employed for the removal of the cream, centrifugal machines performing the process more completely than the old method.

Skim-milk varies in composition for the same reason, but the percentage of sugar is always higher than in uncreamed milk.

Devonshire Cream is of a pasty consistence. It is obtained by keeping the milk in large pans at a moderate heat for a prolonged period, and removing the scum that rises to the surface.

Butter-milk, though it is what is left of the milk after removal of the butter by churning, yet contains a quantity of butter in minute particles. Owing to the souring which has taken place, however, much of the sugar is converted into lactic acid, though it is stated in the table as sugar, and the longer it stands the more complete does this conversion become. It is rich in nitrogen, and with other food is a valuable article of diet.

Percentage Composition of Condensed Milk.

	Anglo-Swiss Coy.'s, made in Switzerland.	Made in England.	American (no Cane-sugar added).
Water,	24·13	24·99	48·59
Nitrogenous,	13·67	10·02	17·81
Butter,	8·67	10·88	15·67
Milk-sugar,	10·82	11·92	15·40
Saline,	2·23	1·96	2·53
Added Cane-sugar	40·48	40·23	——

Condensed Milk.—The above analyses give a fair idea of the average composition of condensed milk. The usual method of preparation is to evaporate the milk in vacuum-pan and then to heat to the boiling point, cane-sugar being added. The milk is then preserved in tightly-soldered tins, so that air has no access. In other cases the milk is concentrated, no cane-sugar being added, so that the simple milk deprived of most of its water is obtained. Of the former kind two analyses are given, showing fully 40 per cent added cane-sugar. This makes such milk exceedingly sweet and unpleasant to many people, though the presence of the sugar enables the milk to keep for a considerable time after the tin has been opened. Of the unsweetened kind one analysis is given. It keeps for a much shorter time after the tin has been opened. On the other hand, it will be observed that this latter kind contains, weight for weight, much more actual milk solids than the former. Thus the unsweetened contains, in 100 parts, 51·41 parts of the actual solids of milk, curd, butter, milk-sugar, and salts, while the sweetened variety contains, in 100 parts, only 35·39 of actual milk solids, though the total solids in 100 parts are brought up to 75·87 by the added cane-sugar. To put it in another way, by the lowest estimate good milk contains not less than 9 parts in 100 of solids, not counting butter. If, therefore, the total solids, excluding butter, present in a sample of condensed milk, be divided by 9, the figure obtained will indicate the amount of condensation to which the milk has been subjected, and, therefore, the original quantity of milk represented by the condensed sample. Thus, in the third analysis given above the total solids, excluding butter, are—

Nitrogenous, ...	17·81
Milk-sugar, ...	15·40
Saline, ...	2·53
	35·74

which, divided by 9, gives 3·97,

as nearly as possible 4. That is to say, the milk has been concentrated 4 times, or the 100 parts condensed milk represent 400 parts of the original milk. If one table-spoonful of this condensed milk be made up to four table-spoonfuls with water, one has restored the degree of strength of the original.

Now take the first sample, it contains of solids, not including butter,

Nitrogenous, ...	13·67
Milk-sugar, ...	10·82
Saline, ...	2·23
	26·72

which, divided by 9, gives 2·97, say 3.

This milk has been concentrated only 3 times; 100 parts represent only 300 of the original, and one table-spoonful would stand bringing up to only 3 with water to restore the original strength. Of course it has, in addition, cane-sugar, but when one buys condensed milk it is not cane-sugar one pays for, and when one feeds an infant on condensed milk it is not syrup one wishes to give.

The use of the simple rule given above will enable consumers of condensed milk to measure exactly what they are doing. When they buy the tin of milk, if its composition is not stated on the tin, let them ask for a note of its composition. The dealer who supplies it will also be able to obtain this for them. With the table of composition before them, let them sum up the total of the percentages of "solids not fat," that is, the totals of the nitrogenous or albuminoids, the milk-sugar (not the cane-sugar), and the saline, and divide the total by 9. They will thus know how much to bring the condensed up to with water to get the composition of pure

milk, and if it is for an infant it can then be further diluted according to the age of the child.

Percentage Composition of Koumiss.

Water, ...	87·87
Nitrogenous, ...	2·83
Milk-sugar, ...	3·76
Lactic Acid, ...	1·06
Butter, ...	·94
Alcohol, ...	1·59
Carbonic Acid, ...	·88
Saline, ...	1·07

Koumiss is obtained from milk by fermentation. It is specially a drink of the Tartars, and is prepared by them from the milk of the mare. Camel's milk is used for its production by the Arabs. Other kinds of milk may also be employed. Cows' milk sweetened is used in London. The actual composition of the koumiss in each case will depend upon the milk used. The Tartars add 10 parts of fresh warm milk, in which a little sugar is dissolved, to one part of milk already soured by standing. Fermentation proceeds, by which the sugar is converted partly into lactic acid, and alcohol and carbonic acid are produced. Its use is largely extending. It is nutritious, easily digested, and has some slight stimulating property on account of the alcohol contained in it. Fashion has perhaps as much to do with its employment in cases of disease as any actual benefit derived from it. It is specially extolled in the treatment of consumption.

CHEESE.

Cheese is chiefly the curd of milk, containing also a proportion of fat, entangled in the curd, varying in quantity according to the quantity of fat present in the milk from which the cheese is made, and a small quantity of the saline constituents of the milk. A small quantity of milk-sugar is present, chiefly in soft cheeses, but it undergoes alteration in process of ripening.

Fresh milk is warmed to a temperature of 80° F., and then rennet, made from the calf's stomach, is added to it along with a proportion of colouring matter, usually annatto.[1] It is allowed to stand for an hour, by which time the curd has formed. The curd is then cut up into small pieces and the whey poured off. Some of the whey is heated and poured over the curd to scald it. The curd is then removed, put into a vat, and placed under a press to expel the whey. The curd is thereafter broken up again and mixed with salt, two pounds of salt to the hundredweight of curd. The cheese is then pressed in a mould. It is then bandaged with cloths, removed from the mould, placed aside, and turned daily for five or seven days. It is then removed to the shelf of a room, kept at a temperature of 75°. It is daily turned, greased and polished, and after three or four months is ready for use. Large factories, fitted with all sorts of mechanical contrivances for carrying on the process of cheese-making, now exist, especially in America, and the cheeses they produce are of a more uniform quality. While rennet is usually employed, acid—vinegar—and other agents for curdling, may be made use of, and cheese may be made from sour milk without the addition of any such agent, the natural production of lactic acid causing coagulation.

The richness of the cheese in fat depends upon the milk used. Whole-milk cheese is made from the fresh milk, without skimming; and examples of this kind are Cheddar, Dunlop, and American. When whole-milk is used with the addition of some cream—the whole-milk of the morning and the cream of the previous evening's milking—a richer cheese is produced such as Stilton. Single Gloucester is made from a mixture of the entire milk of the morning

[1] Annatto is a dye obtained from the pulp, with embedded seeds, of a small South American tree, *Bixa Orellana*. It is very commonly adulterated with turmeric, red earths, red-lead, copper, and other substances. Its use is not to be commended.

and the skimmed milk of the previous evening; double Gloucester is made from entire milk. Neufchatel, Camembert, and Fromage de Brie are cream-cheeses. Roquefort is made from the milk of the ewe, and is kept at a uniformly low temperature during the ripening process, for which purpose the cheeses are kept in subterranean cellars. Skim-milk cheese is poor in fat. Dutch and Parmesan are examples. If the milk has been skimmed twice a very poor cheese is obtained. There is a very hard kind of cheese produced in Suffolk from milk skimmed several times, concerning which it is said that it often requires an axe to cut it, "that pigs grunt at it, dogs bark at it, but neither of them dare bite it."

From 9½ to 10 pounds of milk are required to make 1 pound of whole-milk cheese—that is to say, about a gallon of milk yields 1 lb. cheese. One cow will yield from 3½ to 4 cwt. of cheese per annum.

In the ripening of cheese various chemical changes occur, which make the cheese more readily digested than when it is fresh. Both the curd and the fat undergo changes of a fermentive kind. By the same process the peculiar flavour of the cheese is developed. In the process of ripening a mould appears, common vegetable fungoid growths developed from spores that have gained entrance to the cheese in course of manufacture. These vegetable moulds grow at the expense of the substance of the cheese, and therefore diminish its absolute nutritive value. On the other hand, they add to its flavour and its digestion, probably to some extent mechanically by the fine veinlets of mould permitting the cheese more readily to crumble down and be attacked in smaller particles by the digestive fluids. The cheese-mite, or *Acarus domesticus*, is produced from the eggs of the insect sown in the curd. Cheese-maggots are the larval stage of a fly, the cheese-fly—*Piophila casei*. These may be destroyed by strong heat or immersing the cheese in whisky.

It will be noticed from the tables of composition that cheese is rich in nitrogenous ingredient and fat, whole-milk cheese containing these to the extent of over two-thirds. While this is so, there is a difficulty in making use of these nourishing ingredients from the solidity of the mass, and thus cheese is used rather as a mere adjunct to food than for its nutritive value. Cream-cheeses are usually more easily digested, because the large proportion of fat makes them crumbly and more easily broken down. When cheese, however, is mixed with other food-stuffs, as with corn-flower, bread, &c., when grated to form cheese-pudding, these ingredients separate up the cheese particles; and then a quantity may easily be taken—sufficient to be of considerable nutritive value. Such additions also make up what is deficient, indeed practically wanting in cheese, the starchy or sugary element. It may further be noticed that the saline constituents of cheese are rich in phosphates, of value in bone formation. In a sample of double Gloucester of a total of 4·9 per cent salines, phosphates contributed 3·1.

Various Animal Foods Compared.

It will now be of interest and value to compare the relative richness in nutriment of the various animal foods we have considered. For that purpose I shall place alongside of one another the composition of the chief kinds of such food from the tables already given:—

	Lean Beef.	Bacon.	Fowl.	Egg.*	Cod.	Milk.	Cheese (Cheddar).
Water	72	13·9	73·15	71·7	77·5	86·87	27·83
Nitrogenous	19·3	9·0	22·65	14·0	18·5	4·65	44·47
Fat	3·6	74·1	3·11	11·0	3·0	3·50	24·04
Sugar	—	—	—	—	—	4·28	—
Saline	5·1	3·0	1·09	1·3	1·0	0·70	3·66

* 2 per cent of extractives and membranes omitted.

If we exclude water and salines then from the above tables, we find that 100 parts of each food-stuff contain of nourishing materials the following amounts:—

Beef, ...	22·9	Cod, ...	21·5
Bacon, ...	83·1	Milk, ...	12·43
Fowl, ...	25·76	Cheese, ...	68·51
Egg, ...	25·0		

This shows that beef, bacon, fowl, egg, and cod come very near to one another in the proportion of nourishing material they contain. Cheese stands high in the list, but it is really in a different class from the others, because it cannot be eaten in any quantity, and is really a food adjunct, and cannot take the place of a chief article of diet. Allowing, then, for variations in composition, we may say that, weight for weight, beef, bacon, fowl, egg, and cod are comparatively nearly of equal nutritive value, considering the total nutriment each contains. Considering the details of the composition, we see how alike beef, fowl, and cod are, and how one could readily take the place of the other in a diet, without any deficiency in a particular ingredient arising from the change. It is specially interesting to note how completely fish may

take the place of beef; and, when we remember the marked difference in price between the two, this is a point worthy of being brought markedly into prominence. It is an irresistible plea for the more extended use of fish in the diet of the people. Bacon heads the list; but the small proportion of nitrogenous material and the excess of fat exclude it from entering into serious competition with the other three, though it is nevertheless a highly valuable food-stuff. It is evident also that egg occupies a similar platform to beef, fowl, and fish, and at any rate does not possess any marked pre-eminence. It has no right to be considered, as it so commonly is, a concentrated food-stuff.

II. Non-Nitrogenous Animal Foods.

BUTTER AND BUTTER SUBSTITUTES, LARD AND DRIPPING.

Percentage Composition of Butter and Oleo-margarin.

	Butter.	Oleo-Margarin.
Water	9·40	10·50
Nitrogenous (Curd).	1·40	—
Fat	86·50	87·00
Milk-sugar	·80	0·70
Saline	1·90	1·8

Butter, though consisting mainly of milk-fat, contains a small proportion of the other ingredients of milk. Butter may be made directly from the sweet milk, but usually is made from cream. Rather more butter is obtained from the whole milk, but the process is more laborious, because of the large bulk of fluid. It takes about 23 pints of milk to yield 1 lb. of butter. A good cow will yield 8 to 12 lb. of butter a week during the season; and well-selected cows will yield on an average 2 to 2¼ cwt. of butter per year. The milk is placed in shallow pans and kept at a temperature of about 60° F., at which temperature the cream rises best. Once or twice in twenty-four hours the cream is removed, and placed in a crock till sufficient has been collected. Sometimes annatto is added to it to give a colour, or grated carrots are steeped in it and strained out next morning for a like purpose. In large establishments for the manufacture of butter, the cream is now separated by centrifugal machines. Owing to the keeping the cream becomes slightly sour, because of the change of some of the milk-sugar into lactic acid. This facilitates the separation of the butter, though butter made from sweet cream has a pleasanter taste, and is said to keep much longer. The cream is then placed in a churn, of which there are many forms. Whatever their form, the purpose is the same, namely, by mechanical agitation of the milk globules to break the fine film of albumin which surrounds them, and thus to permit the escape of the oil. The fat thus released runs together, and lumps of butter are produced. The cream is put into the churn at a temperature of about 60° F., at which it is kept. The churning process occupies from thirty to forty-five minutes. The butter is then collected, washed in cold spring-water, to rid it as much as possible of the other elements of milk, and is then kneaded to express the water. It is thereafter mixed with salt as a preservative. In fresh butter there is always added salt to the extent of ½ to 2 per cent. Salt butter contains from 3 to 6 pounds of salt to every 112 pounds of butter, and if it is to be kept for an unusually long time a little sugar is added, not exceeding 8 ounces to every 112 pounds. During the whole process great care requires to be taken to ensure the cleanness of the vessels, churns, &c. used, and of the atmosphere in which the butter is kept. For butter very readily acquires a change of flavour from odorous or smelling substances in its neighbourhood, as well as from any highly-flavoured food eaten by the cow. While the above table gives a fair average composition, very varying results are obtained from different samples. The quantity of curd, milk-sugar, and water will depend upon the care and thoroughness with which the butter has been washed and pressed. An increase in the quantity of curd present diminishes the keeping quality of the butter, from the tendency of the curd to undergo decomposition. The milk-sugar and curd are present in too small quantity to impart any nutritive quality of any consequence apart from the fat.

There is a simple method of making a rough estimate of the quantity of the three chief constituents, which will aid in determining the quality of any particular sample of butter. Place some butter in a test-tube, and melt it by immersing the tube in warm water. As soon as the butter becomes liquid, it will separate into its chief constituents, a layer of water at the bottom, a layer of oil on the top, and between the two a ring of curd. The water should form little more than an eighth of the total liquid in the tube, the oil should form the remainder, the ring of curd being of no marked extent. Any adulteration with water would be quickly detected by such a simple method as this, and any excess of salt would also be noticed. Butter fat is a very complex substance. It is a mixture of various fats, the chief being olein,

stearin and palmitin, and butyrin; while, in small quantity, there also exist other fats, called caproin, caprylin, and rutin. Each of these fats is a chemical compound of a fatty acid and glycerin. Thus oleic, stearic and palmitic, and butyric acids are the acids which, in combination with glycerin, yield the fats olein, &c. The oleic, stearic, and palmitic acids do not dissolve in water, but the others do dissolve. Now sometimes a bad flavour is formed in butter by the decomposition of the butyrin and caproin into their respective fatty acids. These being soluble, the bad flavour may be removed by washing the butter.

In 100 parts of butter-fat the proportion of the several fats is as follows:—

Olein	42·21
Stearin, Palmitin	50·00
Butyrin	7·69
Caproin, Caprylin, Rutin	0·10

Although the last four fats exist in comparatively small quantity, it is they which give to butter its peculiar flavour, distinguishing it at once from other animal and vegetable fats, and it is on the quantity of these last four that analysts mainly depend for distinguishing between pure butter and manufactured substitutes, as will be seen from the analysis given below of the fat of oleo-margarin.

Oleo-margarin, margarin, or **butterine** are various names given to articles manufactured from various animal fats as substitutes for butter. The process is briefly as follows:—Beef fat is principally used. It consists chiefly of stearin, margarin, and olein. It is melted by means of hot water, when the animal fat separates as a yellow oil, water and solid particles sinking to the bottom. A scum of impurities forms on the surface, which is removed, and the oil is run into troughs, where it is kept till much of the stearin crystallizes out. The oleo-margarin is afterwards removed and filtered through cotton, the separated stearin being afterwards used for the manufacture of candles. The oleo-margarin is put into a press and then churned with milk, it being itself quite tasteless, to give it the flavour of butter. It is next coloured, and, after rolling with ice, is packed for use.

As will be seen from the table the composition of oleo-margarin does not differ materially from that of butter. It is indeed a matter of difficulty for experts to distinguish well-made oleo-margarin or butterine from pure butter. Chemists agree in declaring wholesome butter substitutes to be as valuable a food-stuff as pure butter, and to be really not one whit inferior. Its cheapness brings it within the reach of many who find it difficult to purchase the real article. The prejudice against its use is not justified. It is, unfortunately, too often the case that butterine is sold as real butter, and at, or nearly at, the price of the native product. If the people would put prejudice aside, and instead of buying inferior kinds of butter, be not ashamed to buy good quality of butterine or oleo-margarin, they would get an article not easily distinguished from the best butter, at a much more moderate cost. Legislation, instead of hampering the manufacture and sale of these butter substitutes, is now endeavouring to secure that butter substitutes shall not be sold under the name and at the higher price of butter. Chemists distinguish between pure butter and butter substitutes by the proportions of the various fats in each. The fat of oleo-margarin contains:

Olein	30·4
Stearin	46·9
Palmitin	22·3
Butyrin, Caproin, Caprylin	0·4

The marked deficiency in the last three fats as compared with their amount in true butter is evident by comparison with the table of composition of butter-fat given above.

Lard is the fat of the pig melted out from the tissue of which it formed a part. This is done by cutting up the fatty tissue into small pieces and placing them in vessels, usually made of iron, heated by steam. As the fat melts, any water and debris fall to the bottom, and other impurities rise to the surface. The pure lard is run off into bladders or kegs. Pure lard should have no smell and almost no taste, and should be quite free from colour. It usually contains nearly 10 per cent of water, though by various methods it may be made to take up a much greater quantity than this. Smith states that lard should contain 8,237 grains of carbon per pound, the hydrogen it contains being reckoned as carbon (see p. 532).

Dripping is fat obtained in the process of roasting flesh. It is almost a pure fat, and differs from lard mainly in the flavour it has derived from the meat. Both lard and dripping are highly valuable as energy-yielding food-stuffs.

THE COMPOSITION OF VEGETABLE FOODS.

I. Nitrogenous Vegetable Foods.

THE CEREALS OR GRAINS.

Average Percentage Composition of Grains.

	Wheat.	Oats.	Rye.	Barley.	Indian Corn or Maize.	Rice.	Millet.	Buckwheat.	Dhurra, Indian Millet.
Water	13·56	12·92	15·25	13·78	13·88	14·41	11·26	13·4	12·2
Nitrogenous	12·42	11·73	11·43	11·16	10·05	6·94	11·29	15·2	8·2
Fat	1·70	6·04	1·71	2·12	4·76	0·51	3·56	3·4	4·2
Starch, Sugar, &c.	67·89	55·43	67·83	65·51	66·78	77·61	67·33	63·6	70·6
Fibre	2·66	10·83	2·01	4·80	2·84	0·08	4·25	2·1	3·1
Saline	1·77	3·05	1·77	2·63	1·69	0·45	2·31	2·3	1·7

With one exception all the substances mentioned in the above table belong to the natural order of the grasses (*Graminaceæ*). The term "cereals" is employed to include them, meaning the fruit of such grasses as are used for food. Buckwheat is not a grass, but belongs to the same natural order as rhubarb and dock (*Polygonaceæ*). It is used pretty much as are the grains, and, therefore, we may consider it here.

The nutritive value of all these substances is clearly evident from the above table. The analyses of the first seven are from a German source (Kœnig), and represent the average of several hundred analyses; the last two are from an English source (Church).

If we leave out the water, the fibre, which is non-digestible, and the saline constituents, then we find that some of these seeds contain as much as 85 parts (rice) of nourishing material in the 100, while only barley and oats fall below 80 per cent. In regard to oats, I do not think the table above does it justice. Its total nutritive material is represented as falling as low as 73 per cent. Nowhere are oats used so largely or grown to such perfection as in Scotland, and the above table is not a fair representative of good Scotch oats. But I preferred to give the analyses as nearly as possible all from the same authority, to make comparisons more fair, and therefore have not substituted another analysis in this case in place of Kœnig's. An analysis of six samples by Fehling gave from 80·93 to 82 per cent of nutritive material. Without doubt the finest qualities of oats contain an excess of nutritive material over that of the finest English wheat.

When the details of the composition are examined some very interesting facts are brought out. They all contain both the tissue-repairing and the energy-yielding kinds of food-stuffs. In all of them the energy-yielding food-stuffs, starch, sugar, and fat specially abound, though the tissue-repairing material (nitrogenous) is in very good proportion. According to the above table the following is the order of richness in nitrogenous or proteid substances:—

Buckwheat.
Wheat.
Oats.
Rye.
Millet.
Barley.
Maize.
Dhurra.
Rice.

The following is the order of richness in fat:—

Oats.
Maize.
Dhurra.
Millet.
Buckwheat.
Barley.
Rye.
Wheat.
Rice.

The following is the order of richness in carbohydrates (starch, sugar, &c.):—

Rice.
Dhurra.
Wheat.
Rye.
Millet.
Maize.
Barley.
Buckwheat.
Oats.

If we take all three nutritive materials, then, of the ordinary grains used as food oats and wheat rank highest, and, considering the finest qualities, oats have the pre-eminence.

Wheat is an annual grass, of which there are several species. That commonly grown in England is *Triticum vulgare*, of which there are two varieties—summer and winter wheat (*Triticum æstivum* and *T. hybernum*). It is culti-

vated in nearly all temperate climates, but more in the northern than southern hemispheres. It varies much with the soil on which it is reared, and with the dryness or wetness of the season. There is the hard wheat, such as is grown in Odessa, Africa, and Egypt. It is horny and semi-transparent in appearance, is specially rich in nitrogenous or proteid material, and less rich in starch than the average shown in the above table. It is from such kinds that macaroni and vermicelli are prepared. The soft or white wheat is more tender and floury, is more easily ground, contains more starch and less nitrogenous material, and makes a finer flour. There is an intermediate variety grown in France.

Wheat, as supplied to the miller, is deprived of its husk. The seed consists of an outer portion, formed of a series of coverings or membranes, and of an inner part, the substance of

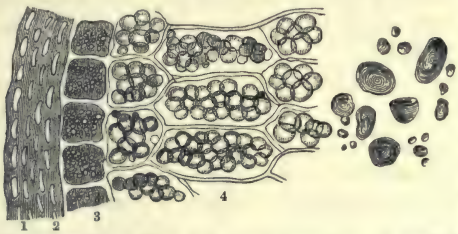

Fig. 194.—Section of Wheat Grain—highly magnified. To the right the granules of wheat starch are shown more highly magnified.

1 indicates the outermost seed-coat, formed of several rows of thick-walled cells, 2 is an inner fine seed-coat, and 3 are called the gluten cells where the cerealin is found. All these yield the bran. 4 points to the compartments filled with starch grains.

the seed itself, divided off into compartments in which are starch grains. The figure (Fig. 194) shows these different parts when a thin slice, taken across a grain of wheat, is examined under a highly magnifying microscope. The various coverings are removed in the process of grinding and dressing for flour and form the bran, while it is from the starchy centre that the fine flour is made. The branny coatings are specially rich in nitrogenous material, though the starchy centre is not by any means devoid of it, the compartments in which the starch grains lie being formed of albuminoid material. It appears that the innermost layer of the seed covering (3 of Fig. 194) is richest in albuminoid material. In this coat there is also present, it appears, a ferment (cerealin) capable, under proper conditions of heat and moisture, of converting the starch of the grain into sugar.

Whole wheat is hardly at all used for food; but it once made a popular dish in England, called **frumity or furmenty**, which is still occasionally seen in Yorkshire. It was a common dish in harvest-home celebrations. In its preparation new wheat was steeped in water in a pan, placed in the oven and kept at a temperature of about 120° Fahr. for some eighteen to thirty-six hours. Not only did the grain swell in the process, but by the heat and moisture the ferment was enabled to act upon the softened and ruptured starch grains, converting them into sugar. The grain was then boiled with milk; and sweetening and spice were added. It is said to be a delicious dish, but the presence of the husk and bran made it indigestible.

By the grinding of wheat various products are obtained. The whole grain may be ground as finely as possible, no part being removed. Modern methods of milling now make it possible for very much finer whole meal to be placed in the market than formerly. Some of the objections to whole meal have thus been removed. The branny portions are not easily reduced to a fine condition, and if they are present in the meal in particles of any size, not only are they indigestible, but their roughness and their sharp edges irritate the bowels, and so stimulate them as to cause the food to be hurried along the bowel before the nutritive material can be extracted from it. Indigestible themselves, they thus also prevent the due digestion of other food. The grinding of wheat has now, however, become a very elaborate process, and in mills, constructed and furnished in the most approved fashion, a very large variety of products is obtained from the wheat. The wheat is passed between rollers, in which it is submitted to a cracking and squeezing action, the purpose of which is to enable the kernel to be separated from the other coverings. It is passed through a series of rollers, five, six, or seven, being submitted between each "break" to a series of sifting and winnowing and dressing operations, by which branny particles are separated out, and the flour which the "break" has produced is sifted out, the intermediate portion being passed on to the next roller, and so on. Thus, after it has passed through two or three rollers, branny portions have been largely removed, and the product is white and granular, consisting chiefly of the kernel of the grain broken up into coarser or finer particles, according to the exact number of rollers through which it has passed. To this product of the wheat, in its conditions of coarse or fine particles, the name **semolina** is given. By further operations of rolling, dressing, &c., it may be reduced to the form of flour. Various terms are applied to the differ-

ent products obtained in the various stages of the milling process. A simple division of the products is into flour, middlings, and bran. Of the bran, even, there are many degrees of fineness. Thin bran is that part of the covering which is often separated before the grain is broken according to one method, that of Mège Mouriés, by damping and rubbing the grain. Then there is long bran, the next outermost coat of the grain. Pollard is a finer bran. Middlings consist of fragments of the kernel of the grain mixed with branny particles, and as they are submitted to further rolling they become reduced and separated by winnowing, &c., from the branny portions. Tailings is a term applied to lighter portions of the wheat, separated out by winnowing, consisting of parts of the kernel adhering to the bran, which, by subsequent breaking, become separated, so that finally the tailings become reduced to simple bran. Sharps is the product a stage behind the fine flour, in which the starchy part of the grain is yet in particles, and in which some of the outer parts of the seed are still present, though in a fine state of division. Fine sharps is also called seconds flour, and coarse sharps thirds. It is worth noticing those different varieties, because their chemical composition is different. The chief difference consists in the varying proportion of nitrogenous material which each contains. As already noted, the outer parts of the grain are richest in nitrogenous or albuminoid material, and the kernel is richest in starch. Accordingly, as the coarser portions are removed, and the stage of fine white flour is reached, the proportion of albuminous material falls, and that of starch rises, so that the finest white flour, consisting essentially of the heart of the grain, is poorer in tissue forming and repairing material than the inferior qualities of flour, in which a larger proportion of the outer parts of the wheat is present. This is well shown in the following note, taken from Church, of the relative proportion of the nitrogenous material in one pound of some of the products named:—

				oz.	grs.
1 pound of finest flour contains of nitrogenous			material,	1	297
,,	middlings	,,	,,	2	105
,,	coarse sharps	,,	,,	2	246
,,	fine pollard	,,	,,	2	210
,,	long bran	,,	,,	2	182

In the outer parts of the grain, also, the saline constituents reside in greatest abundance. Thus they amount in fine flour to 50 grains in the pound, in middlings to 147 grains, in fine pollard to 399 grains, and in long bran to 1 ounce 60 grains. Much of the saline material consists of phosphates, of great value in the formation of bone. Thus a seconds flour is superior to the finest quality from a nutritive point of view, because of the larger proportion of material useful for the repair of all the tissues and the formation of bone. It might also be said, at least so far as the chemical composition is concerned, that a still lower quality of flour possessed a higher nutritive value. But when one takes coarser kinds, the element of digestibility enters into the question. It has been shown, by direct experiment, that when bread made from the finest flour was consumed, less was expelled from the alimentary canal in the form of waste than when bread of coarser qualities was eaten. It is not possible, therefore, to make the chemical constitution the only test of the nutritive quality of the flour. The following table shows the differences that have been indicated:—

	Fine Flour.	Whole Meal.	Bran.
Water	13·0	14·0	14·0
Nitrogenous	10·5	21·8[1]	15·0
Fat	0·8	1·2	4·0
Starch, Sugar, &c.	74·3	59·7	44·0
Fibre	0·7	1·7	17·0
Ash	0·7	1·6	6·0

[1] Of which a large portion is not useful for nutrition.

Flour consists, it appears from the table, to the extent of three-fourths of starch, and contains only a tenth of nitrogenous material, with less than a hundredth part of fat. The starch may be separated from the nitrogenous material by a comparatively simple process. The flour, made into a stiff dough with water only, is placed on a sieve or on a piece of muslin tied over the mouth of a wide bowl, and worked with the hand while a stream of water flows upon it. The starch granules pass through the muslin or sieve with the water, and the process is continued till all the granules have been washed away, and the water passes through quite clear. The starch may be recovered from the bowl by decanting the water, as it does not dissolve in cold water, and then drying it. There remains on the muslin a yellowish, semi-transparent, adhesive substance, somewhat elastic, to which the name **gluten** is given. When dried it is a horny, brittle substance. This may be made without further preparation into small rolls or buns and baked in the oven, when one has **gluten bread**. It swells greatly during

baking, so that very small pieces are used for each roll. It is this bread which is used in the treatment of diabetes (p. 303), in which all sugar is cut off from the dietary, and necessarily also all starch, since starch is converted into sugar in the body. There is no grain other than wheat which yields a flour containing so much gluten. It is the presence of the gluten that enables wheat flour to be so readily made into a dough, which can be baked into loaves. Its adhesive and ductile qualities render it possible to bake it into various forms which will retain the shape given to them. But this gluten, or vegetable albumin, as it is also called, is not a simple substance like egg albumin. It appears to consist of no less than four albuminous bodies. One of these is gliadin, "which is like a clear yellow varnish, and so tenacious that it may be drawn into threads." So that it is this constituent of the gluten specially which gives the tenacious character to dough.

Bread is simply baked dough, made with flour and water, a porous or spongy character having been given to the mass. This spongy character is produced by a variety of methods. The one in ordinary use is that of fermentation, and consists in the introduction into the dough of some yeast, which in course of its activity produces alcohol and carbonic acid gas. If the yeast has been thoroughly mixed with the dough the carbonic acid gas is produced uniformly throughout the mass, and thus causes the dough, because of its tenacious character, to rise with the pressure of the generated gas, and to be permeated by a multitude of minute spaces. The gas escapes from the bread, but the fine spaces or cavities remain permeating the bread and conferring a porous character upon it. The nature and action of yeast are described in the next section, in the portion devoted to the consideration of the manufacture of alcohol. Various kinds of yeast are used for this purpose. Barm is the yeast used by brewers to excite fermentation for the manufacture of beer, and is used by some to produce the best-flavoured bread. Leaven is obtained from old dough. If a paste be made of flour and water, and set aside in a warm place, fermentive changes will arise in it, and if a portion of this dough be mixed with fresh dough it will excite the change quickly in the latter. The cause of the fermentive change is really the same in leaven as in yeast, the action of the yeast plant, which in the former case has been deliberately introduced, and whose introduction has in the latter case been left to chance. The leaven is, on that account, apt to become the scene of abnormal forms of fermentation of an acid kind, and to produce a souring action on the dough rather than a true leavening action. Bakers' yeast is a preparation of boiled and mashed potatoes to which yeast and flour are added, the potatoes affording nutriment for the growth of the yeast. Patent yeasts are now extensively employed. They are produced by scientific methods from malted grains, as in the production of alcohol; mixed with starch and filtered, the yeast can be pressed into cakes, in which form it is easily kept and transported. Such yeasts are imported principally from France, Germany, and the Netherlands.

In the making of bread a portion of the flour is mixed with the ferment with water and salt. The mass produced is set aside, and forms the "sponge." It is left for several hours, during which fermentation occurs and the sponge rises, and latterly collapses by escape of gas. Thereafter the remainder of the flour, with additional salt, is incorporated with the sponge, forming the dough, which is thoroughly kneaded. It is then allowed to lie for a couple of hours longer, when it is turned out of the trough, and weighed out into the required masses, which are shaped into loaves for the oven. With the heat of the oven the gas, entangled in the dough, expands and causes a further "rising" to take place; and with the continuance of the heat the yeast is killed, so that no further fermentation can occur. The dough can be made porous by other methods not involving fermentation. Tartaric acid and carbonate of soda mixed with the dough will cause it to rise, because the chemical action of the two produces carbonic acid gas, which expands the bread. This process was devised by Dr. Whiting in 1836. He, however, used hydrochloric acid added to the water, the carbonate of soda being mixed with the flour. In 1845 tartaric acid was substituted for hydrochloric. Baking-powders are made of mixtures of tartaric acid and soda, and sometimes they are coloured yellow with turmeric and called *egg-powders*, though they are quite innocent of any acquaintance with eggs. Another method of raising bread was patented by Dr. Dauglish in 1856. It consists in making the flour into dough with water charged with carbonic acid gas, and the bread produced was on that account called "aerated bread." The carbonic acid gas is produced first, and is dissolved in water under pressure, a simple aerated water being produced. In another strong iron vessel called a "mixer" the

flour is made into dough with the aerated water by the action of "arms" worked by machinery. The gas passing off from the water permeates the bread, and when the dough shaped into loaves is turned out of the machine, it expands still further. During the whole operation it is untouched by the hand. From the absence of the chemical changes occurring in fermented bread, the flavour is not so complex, nor so enjoyable, as that of the fermented variety. The addition of carbonate of ammonia to dough will also cause "rising" to occur by the production of vapour of ammonia, owing to the heat, and its dissemination through the dough. It will be noticed that whatever method is employed, the chief result desired is that of permeating the bread with air spaces to confer lightness and sponginess upon it, and render every particle of it more easily accessible to the action of the digestive fluids, and therefore more readily digestible.

There are considerable chemical differences between ordinary bread and the flour from which it is made, changes produced by the process of baking, and the changes set up by the fermentation. The baking causes the starch grains to swell and burst, rendering their contents accessible to the digestive fluids. The albuminous substances are coagulated, and can no longer be separated from the starch. Some of the starch is changed into dextrin, a form of sugar, by the action of heat, and this specially occurs in the crust. Some of the starch will also be converted into sugar by fermentive changes which occur if the flour contains any of the cerealin of the grain. Bread contains, therefore, always more sugar than is present in flour. While the bulk of alcohol produced by the process of fermentation escapes, an appreciable quantity can always be detected in fresh bread. "A pound loaf would yield, if very carefully distilled, about twenty-two grains (considerably less than a tea-spoonful). As the bread gets staler the quantity decreases." The following table shows the composition of fine white bread:—

	Fine White Bread.
Water	38·51
Nitrogenous	6·82
Fat	·77
Starch, Sugar, &c.	52·34
Fibre	·38
Saline	1·18

The amount of water present in bread should not exceed that stated in the table. But supposing flour were made to take up more water than usual, it is evident that a larger quantity of bread than usual could be produced from a given quantity of flour, to the profit of the baker. This is one of the chief reasons for the adulteration of bread with alum, rice, &c. Dr. Letheby says, "in practice 100 pounds of flour will make from 133 to 137 pounds of bread, a good average being 136; so that a sack of flour of 280 pounds, should yield 95 four-pound (quartern) loaves. The art of the baker, however, is to increase this quantity, and he does it by hardening the gluten through the agency of a little alum, or by means of a gummy mixture of boiled rice, three or four pounds of which will, when boiled for two or three hours in as many gallons of water, make a sack of flour yield 100 four-pound loaves. But the bread is dropsical, and sets soft and sodden at the base, where it stands." The method of detecting these adulterations is mentioned on p. 597.

Bread loses weight by evaporation of water. The 4-lb. loaf loses on an average

In the first	24 hours	1¼ ounce.
,,	48 hours	5 ounces.
,,	60 ,,	7 ,,
,,	70 ,,	8¾ ,,

—(Blyth.)

Bran bread, and specially whole-meal bread, show a larger proportion of nitrogenous constituents, but for reasons already stated, it is not likely that it yields any appreciably larger quantity of nourishment to the body, though for many persons its action on the bowels is of considerable value.

Malted bread is bread prepared with malt, by means of which a considerable quantity of the starch of the flour is converted into sugar, and by this means the digestive organs are relieved of some of the work they would otherwise be called on to perform.

Biscuits are usually unleavened. The simplest sailors' biscuits, for example, are made with flour and water, and with, perhaps, a slight addition of butter. Fancy biscuits are made with special qualities of flour, and contain, besides the ordinary ingredients, milk, salt, butter, sugar, perhaps eggs, and any special flavouring or colouring agent. They are sometimes "lightened" by means of carbonate of ammonia. Because of their dryness they keep well. They are as a rule exceedingly wholesome, and contain more nutriment than an equal weight of bread. Biscuit powder boiled with milk, or a mixture of milk and water, and slightly sweetened is a useful food for infants. Tea

biscuits ground by means of a rolling-pin may be used for this purpose.

Passover cakes are a form of unleavened bread. They are made of flour and water only.

Semolina, as already described, consists of the heart of the wheat grain in a yet granular condition. It is largely starchy in composition, and is not, therefore, suitable as a main article of diet. It is, however, usually made from the hard wheats of warm climates, and thus contains a larger quantity of nitrogenous constituent than that made from ordinary white wheat.

Macaroni, Vermicelli, and Cagliari Paste are also prepared from the hard wheat. A paste is made of flour and hot water, and is pressed through moulds to produce the pipe form, or stamped out into the desired shape. It is then dried. Such preparations of wheat contain a much higher proportion of nitrogenous material than bread. They are exceedingly nourishing in consequence, if less digestible because of their close texture.

Oats are derived from an annual herbaceous grass, of the tribe *Aveneæ*. The common oat

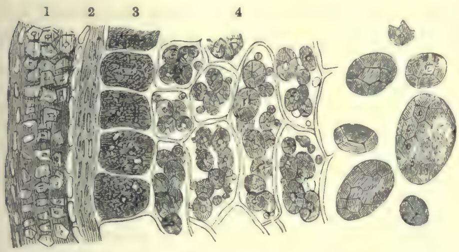

Fig. 195.—Section of Oat Grain—highly magnified. 1 and 2 are the membranes enveloping the seed, corresponding to the bran of wheat. 3 is the surface layer of the seed itself. 4 are the compartments containing starch granules, into which the substance of the seed is divided. To the right of the fig. are shown some of the granules of starch from the interior, more highly magnified.

is derived from the *Avena sativa* or *orientalis*. It is a hardier plant than wheat, ripening well in colder climates. Grown in England as food for horses, it was long the main, and in a large number of cases the only, food of the Scotch peasant. A bag of oatmeal was the only ration the Scotch clansman provided himself with, when he sallied forth with his clan to a fray, and the Scotch Highlanders have been considered as one of the most martial and enduring races on record.

Fig. 195 shows a section of the oat grain, resembling that of wheat, the kernel consisting of compartments filled with starch grains, and being surrounded by several coats richer in nitrogenous material. The husk adheres to the grain very closely. For its removal the grain is dried on a kiln, and then by grinding in a mill the grain is broken up, and the husks removed. The oat broken up into coarse particles is called groats or grits, these on being ground form oatmeal. One hundred pounds of oats yield of—

Oatmeal	60 pounds.
Husks	26 ,,
Water	12 ,,
Loss	2 ,,

The composition of a fresh sample of Scotch oatmeal, which possesses the largest nutritive properties, is shown in the following table:—

	Scotch Oatmeal.
Water	5·0
Nitrogenous	16·1
Fat	10·1
Starch, &c.	63·0
Fibre	3·7
Saline	2·1

The small proportion of water is noticeable. The nitrogenous constituent consists of two substances, plant casein or avenine, and gliadin. The former resembles in proporties one of the albuminoids of wheat, and in composition the legumin of peas and beans; the latter is in less quantity than in wheat, and thus a dough cannot be made of the flour of the meal, so that oat bread cannot be made. Oatcakes and biscuits are, however, baked, but because of the very slight tenacious character of the meal, they are very short. A very important element in the composition of oatmeal is the large proportion of fat. No other cereal contains such a large quantity; Indian corn is the only other which yields a meal at all approaching to it. It is this, as well as the larger proportion of the nitrogenous material, and the small percentage of water, that makes oatmeal so exceptionally wholesome and nitritious. The salines consist largely of salts of potash and phosphorus.

A fine oat-flour is now prepared by several millers in Scotland, which contains all the nourishing ingredients of the meal. It is as yet sold at too high a price to make it a very extensively used food-stuff. It forms an admirable diet, when boiled with water, for children. It may be given to them with milk as soon as it becomes desirable to supplement the mother's milk, by the sixth or even the fourth month of life, and it may be made an exclusive diet for them up to the end of the eighteenth month, or for any longer time. One often finds it stated that wheat-flour and oatmeal are, weight for weight, pretty nearly on a level as regards nourishing qualities. This is true of inferior qualities of oatmeal. Oats grown in

England, for example, are much inferior in nutritive constituents to the finest Scotch oatmeal. It is not true of the latter, which in point of nourishing constituents, ease of cooking, and digestibility far surpasses every other kind of food-stuff.

The husks of oats with the adherent particles of the kernel are employed to make what used to be a very popular dish in Scotland and South Wales, and called **sowans, seeds,** or **flummery.** The husks are steeped in water for two or three days, till by the action of a ferment, present in small quantity in the coverings of the seed, fermentation arises. The liquid is skimmed and then boiled down to the thickness of gruel. It is called **sucan** or **llymru** in Wales. When it is boiled down for a longer time, it forms a firm jelly on cooling resembling blancmange, which is very light, bland, and nourishing. It is called **budrum. Brose** is prepared by simply stirring in boiling water with the meal. It is eaten with milk. The Scotch farm labourer, with whom it was often the chief if not the only meal, found it more "staying" than porridge because of being less rapidly digested. The water used may be that in which beef has been boiled, and then **beef brose** is the product, or that in which cabbage or kale has been boiled, and the product is **kale brose. Gruel** is made by steeping groats or oatmeal in cold water for several hours, with occasional stirring. The mixture is then well stirred and the water poured off carrying with it the flour of the meal, all large particles being left behind. This liquid is then boiled with constant stirring for 10 or 15 minutes. Milk may be added to it and boiled with it. Sugar, butter, and flavouring agents, such as ginger or raisins may also be added, according to desire. The product is an exceedingly soft, pleasant, and nourishing drink, which is in much favour for the domestic treatment of slight colds in the head, and simple feverish colds, or after hard work and exposure. The common prescription in such circumstances is a hot foot-bath, a gruel, and to bed.

Porridge is made by stirring the meal into boiling water. The water in the pot is allowed to boil first, then a handful of meal is taken, and the meal allowed to fall in a slow stream on to the water, which is continually stirred the while with a wooden stirrer called a porridge-stick or spurtle. From three-quarters to an imperial pint of water and a good handful of meal, about four ounces, are about the quantities to make a good dish for one person. Salt is added to taste. The mixture is kept boiling for fully twenty minutes, by which time the particles of meal have become much swollen and the porridge is thick. Of course it may be made of any desired degree of thickness. The best way to eat it is with cream or milk. Some persons prefer to eat it with butter, or not to add salt and to use sugar, syrup or treacle as an adjunct. But porridge, if properly made, and cream is the dish *par excellence.* The Scot who crosses the border, or the German Ocean, or the Atlantic, and seeks to have his national dish to breakfast, is seldom surprised that its popularity is pretty nearly confined to Scotland. As one finds it served in London or Continental hotels, or in the saloons of Atlantic liners, it is, as a rule, an execrable dish. If properly made few fail to relish and enjoy it. Scotch oatmeal is usually in larger particles than that made in England, and the porridge made from it is usually more enjoyed. Oatmeal is often alleged to be "heating," this view Pereira thinks arises from prejudice and to be without due ground.

Barley belongs to the tribe *Hordeæ* of the grasses. There are several varieties of it. It was originally a native of Western Asia, is hardier than either wheat or oats, and may be grown in high latitudes. It is used in Britain mainly for the preparation of malt, ales and spirits. In Scotland, in the form of pot or pearl barley, it is used for broth, but not for the making of solid food. On the Continent the meal is added to wheaten flour for bread, and is also largely used alone. It may be used whole after being parched. The grain in section presents an appearance like wheat or oats. The grain ground whole yields barley-meal, and it is also, by a process of rubbing, deprived of its coatings and rounded into the form with which one is familiar. The coarsest form is called pot-barley, and the finest pearl-barley. The composition of barley-meal and pearl-barley is shown in the following table:—

	Barley-meal.	Pearl-barley.
Water	15·06	14·6
Nitrogenous	11·75	6·2
Fat	1·71	1·3
Starch, &c.	70·90	76·0
Fibre	·11	·8
Saline	·47	1·1

Patent barley is made by grinding pearl-barley to powder. Formerly barley-meal was largely employed instead of wheat flour as a food for the people. Its nitrogenous constituent resembles that of wheat. Its salts are rich in

potash and phosphorus. It is both less nourishing and less easily digested than wheat or oats, and is not, therefore, equal to them as a food-stuff. The bread it yields is heavy. **Barley-water** is a pleasant, cooling drink in feverish attacks. It is made as follows: take two ounces and a half of pearl-barley, first wash away with water the foreign matters adhering to the seeds, then add half a pint of water and boil for a little while. This liquid being then thrown away, pour on them four pints (imperial) of boiling water, boil down to two pints and strain. It is frequently flavoured with sugar and sometimes with lemon-peel. (Pereira.)

Malt is produced from barley by causing the grain to germinate by means of moisture and warmth. By the activity of a ferment, contained in the coatings of the seed, some of the starch of the grain is transformed into sugar. This is a process preliminary to brewing, for under the influence of an added ferment—yeast—this sugar is further converted into alcohol and carbonic acid gas. This is described in more detail in the succeeding section.

Rye is derived from the *Secale cereale.* It is grown in the eastern counties of England, mainly for malting purposes. The malt used in the manufacture of Hollands is made from rye. It flourishes in soil too poor for wheat. It is extensively used for the production of bread in Northern Europe, the well-known black bread being made from it. Mixed with wheat flour, rye flour is used for the same purpose, two parts of wheaten flour and one of rye flour. The bread is dark and sour and close, though nourishing. The general appearance of a section of the seed resembles that of wheat and oats. Deprived of the husk it is ground into meal and flour. The composition of rye flour and rye bread is shown in the following table:—

Fig. 196.—Spurred Rye.

	Rye Flour.	Rye Bread.
Water	13·0	44·02
Nitrogenous	10·5	6·02
Fat	1·6	·48
Starch, &c.	71·0	47·87
Fibre	2·3	·30
Saline	1·6	1·31

The saline constituents are, like those of the other grains, rich in potash and phosphorus.

It is clear from this table, comparing it with that of wheaten bread, on p. 562, that wheaten bread and rye bread are much alike in nourishing quality, though the former is slightly more digestible. The latter keeps better and does not so quickly become dry and stale.

In Russia rye is used for the production of a fermented liquor called **quass.**

Rye is subject to the attack of a fungus called ergot of rye, or *Secale cornutum,* and the rye attacked is called, from the appearance the fungus produces, spurred rye (Fig. 196). It attacks the ear when it is in flower, the young flower being covered with a white mass, consisting of the spores of the fungus. Ergot is employed in medicine and is an exceedingly valuable drug, but when spurred rye is used for food serious and even fatal consequences are liable to ensue, gangrene of the extremities being produced by the frequent use of the diseased grain. Ergot also attacks wheat and maize.

Fig. 197.—Maize or Indian Corn.
1. The grass. *a a*, Position of the cob. 2, The cob. 3, The corn.

Maize or **Indian Corn** (Fig. 197) belongs to the tribe *Maydeæ* of the grasses, and is called *Zea Mays.* It is native to tropical America, but is now grown also in Africa, Southern Europe, Germany and India. It grows to the height of 6 to 10 feet, the grain growing on a cob, as shown in the figure, several cobs being on each stem. The fruit is in this form called **corn-cob** in America, and is often eaten green, or boiled in milk, or roasted and eaten with other foods. **Pop-corn** is the grain of a small variety of maize burst by the agency of heat. When mature the whole grain may be used after being parched. It is also ground into a meal, skin and kernel together, the coverings

being more easily ground than those of other grains. The grains deprived of the husk and roughly ground yield **hominy, samp,** or **grits,** according to the size of the particles. It needs much boiling, and is the better of being steeped for some hours previous to cooking. The composition of Indian-corn meal is as follows:—

	Indian-corn Meal.
Water	17·1
Nitrogenous	12·8
Fat	7·0
Starch, &c.	60·5
Fibre	1·5
Saline	1·1

It will be noticed from the table that maize meal contains a much larger quantity of nutritive material than all the cereals, oatmeal alone excepted. The quantity of fat present is very high. The nitrogenous ingredient is also abundant, though nearly 2 of the 12·8 per cent is of a kind not available for nourishment to the body. Phosphoric acid and potash are the chief constituents of the saline ingredient.

Maize meal cannot be made into a light bread, but it is cooked in the form of cakes or puddings or prepared as a porridge. Thus in the United States of America a dish called **mush** is prepared from it by boiling. The same in Italy is called **polenta;** a finer meal is termed **polentina. Corn-lob** is a maize porridge made with milk. The brown bread of New England is made of a mixture of maize and rye meal.

Cakes, called **Johnny-cakes,** or hoe-cakes, are made of it and are baked before the fire on a board or on a plate in the oven. In Mexico **tortilla** is the term used for them. They are eaten hot with milk, or butter, treacle, &c.

The objection to maize meal is its flavour, due to the presence of a bitter principle. By various methods of manufacture this principle and the nitrogenous constituents are removed, leaving only the starch of the grain in the form of a fine white powder, called corn-flour, maizena, cornena, Oswego flour, &c. It is really pure starch, and will be considered in detail among the starches.

Rice (*Oryza sativa*) belongs to the tribe *Oryzeæ* of the grasses. It is native to India, and is also grown in China, and the East generally, in Central America, and the southern parts of Europe. It requires a warm climate for its successful growth, and the fields are usually irrigated. There are many varieties, the grains differing in size, colour, and general appearance, that grown in South Carolina being most esteemed. It is cut down and threshed like wheat, and the grains inclosed in the husk are known as **paddy or rough rice.**

The fig. 198 shows a section of the grain. It is the main food of more than a hundred millions of people. It is husked by passing it through a mill, and then the husks are winnowed out, broken rice is separated, and the cleaned kernel is that part sold as rice. Its composition is shown in the table on p. 558, from which it appears to be deficient in nitrogenous material and more than usually rich in starch, and deficient in fat. It is the least nutritious of the cereals, and is not a perfect food alone, because of its deficiency in tissue-repairing material, a deficiency made up by the addition to the diet of some kind of flesh meat, or eggs as in rice-pudding, and to a slight extent by milk. Because of its richness in starch rice is

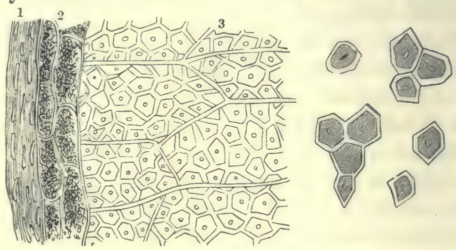

Fig. 198.—Section of Rice Grain—magnified.

1 and 2, Outer coats; 3, Starchy kernel. To the right are seen granules of rice starch, more highly magnified.

used for the production of that article. When cooked alone it should be steamed, not boiled, to prevent the removal of any of the nitrogenous constituents.

Ground rice and rice flour are two products, the latter being often used to adulterate other less cheap kinds of flour, such as that of wheat.

Millet belongs to the species *panicum*, of which there are many varieties. It is native in the East Indies, and is used as food in China and among eastern races, chiefly, that is, in hot countries. The grain is used in this country for feeding poultry and other domestic animals. Its composition is shown on p. 558. Its nutritive value is reckoned as about equal to rice. In the *Lancet* of November 9, 1872, the result of an experiment made with millet is recorded. It was made on a sailor, sentenced to solitary confinement for forty-nine days. He was fed solely on millet and water. "He entered prison on the 3d April, when he weighed 146 lbs. 8 oz., and he left it on the 22d May, weighing 147 lbs. 14 oz. Throughout the confinement he never weighed so little as on the day he commenced, and this in spite of the depressing effects of solitude and the monotony of his food. He ate

about $3\frac{1}{2}$ lbs. of millet daily; and when he left prison he looked, as he said he felt, perfectly well. The experiment shows that the grain, which has been chosen by the people as their principal food, is capable of maintaining for a considerable length of time perfect health under very depressing circumstances.”

Fig. 199.—Millet.

A fermented beverage, called **bouza**, or millet-beer, is prepared from the grain in Tartary, by pouring hot water over a portion of fermented seed. In Sikkim also such millet-beer is in general use. The millet seed is moistened and allowed to ferment for several days. An infusion is then made with hot water, which is sucked through a reed from bamboo jugs. It is said to taste like negus of Cape sherry, rather sour, and though weak a grateful beverage on a hot day's march.

Dhurra, Dhoora, Dari, Sorghum vulgare, or **Sorgho Grass** is a species of millet, Indian millet, but it belongs to a tribe of grasses different from the true millets, namely, *Andropogoneæ*. It is a tall handsome grass which is largely grown in India, Egypt, Algeria, and the interior of Africa, and to some extent in the south of Europe. The grain is white and larger than millet. It is used in this country for feeding cattle and poultry. Its composition is shown on p. 558, from which it appears to be more nourishing than rice, but to contain less nitrogenous material than wheat, though much more fat.

Fig. 200.—Quinoa.

Buckwheat is not a grass, but belongs to the natural order *Polygonaceæ*. It is a native of Central Asia. In France it is called **Saracen wheat**, having been introduced into Europe by the crusaders. In Norfolk and Suffolk it goes by the name of **brank**. It is used in England for feeding game, and sometimes is given to horses. The husk of the seed requires removal before use, and the composition of the grain deprived of the husk is shown on p. 558. It is rich in all the constituents of nitrogenous material, starch and fat. It does not give a tenacious dough for the making of bread, but may, when ground, be cooked as porridge, or made into thin cakes, which is the favourite method of cooking it in America. They are eaten hot with honey or other savoury substance.

Quinoa (Fig. 200) is a seed yielded by a plant, the *Chenopodium Quinoa*, growing in the high table-lands of Chili and Peru. It forms the principal food of the people of the districts where it grows. The order to which it belongs includes the spinach and the beet. It is said by Johnston to be very nutritious, its flour approaching very nearly to oatmeal in composition, and to have formed the chief food of the Peruvian nation. There is a sweet and a bitter variety of it. The meal can be made only into cakes.

LEGUMINOUS SEEDS.

Average Percentage Composition of Peas, Beans, and Lentils.

	Peas.		Broad Beans.		Kidney Beans.		Lentils.
	Green.	Dried.	Green.	Dried.	Green.	Dried.

Saline......	0·80	2·65	0·64	3·15	0·57	3·53	2·47

The natural order Leguminosæ includes peas, beans, and lentils as the chief examples used as food. They belong to the papilionaceous division of that order, so called from the butterfly appearance of the flower (Latin *papilio*, a butterfly). They are all characterized, as the above table shows, by the unusually large proportion of nitrogenous material, excelling beef, mutton, and fish in this respect, and still more markedly other vegetable products. This is strikingly shown in Plate IX. One must not, however, ignore the fact that this nitrogenous constituent is not all available for nutriment, and that a very much larger proportion of waste attends their consumption than that of animal food. This is further referred to on p. 604. Their richness in nitrogen makes them valuable associates in a diet, abounding rather in starch or fat. As an example of the former take rice and peas or beans, and of the latter, bacon and beans or peas.

Peas. There is the garden pea (*Pisum sativum*) and the field pea (*P. arvense*), the latter grown for feeding cattle. The garden pea is native to the south of Europe. The sea pea (*P. maritimum*) is also used in some parts of Europe as a food. The chick pea or gram (*Cicer arietinum*) is grown largely in the North-western Provinces of India, where it is commonly sown with barley and

wheat. "The tops of the shoots are much relished as a vegetable, the flavour being possibly enhanced by the oxalic acid which it is the curious property of the leaves to exude." It suffers greatly by frost, and is not, therefore, a profitable growth in colder climates. It is also cultivated in the south of Europe.

It will be noticed from the table that peas in the fresh state are much less nourishing than when old and dried. They are, however, much more tender and digestible. The skin is particularly difficult of digestion. The chief nitrogenous constituent of peas, beans, and lentils, is a substance called plant-casein or legumin. It is their richness in legumin that gives them the tendency to produce flatulence and colic, when they are eaten to any extent. The saline constituent is richer in potash and lime than that of the grains, but poorer in phosphoric acid. Peas and other members of the same family contain a bitter principle, removable by soaking in water to which a little ordinary washing soda has been added. It is recommended to soak them in this for some time before cooking, the liquid being thrown away. They require prolonged, slow boiling, even when ground. The tough skin is removed in split-peas. The composition of dried peas ground into meal is stated as follows:—

Percentage Composition of Dried Pea-meal.

Water	8·10
Nitrogenous	28·10
Fat	2·97
Starch	50·17
Fibre	8·12
Saline	2·54

Pease-meal is, subject to the remarks that have been made as regards digestibility, an exceedingly valuable article of diet. Stirred with boiling water to a fine thick paste, and with added salt, it forms brose. But it would be of much greater nutritive value, and milder in action on the stomach and bowels, if made into a porridge, by prolonged boiling in the manner of oatmeal porridge. In Germany a pea sausage and pea tablets are prepared from pease-meal and dried and powdered meat, the mixture being compressed by strong pressure. It has been found a very useful ration for the soldier in campaigning. It contains over 31 per cent of nitrogenous, 3 of fatty, and 47 of starchy material, and 2 lbs. of it daily would supply a diet for hard work. Tinned peas are prepared by being submitted to the influence of a high temperature after being placed in the tins, and then the tins are hermetically sealed. Often they have their colour improved by being previously boiled in copper vessels. Though it has not been found positively that this practice is injurious, it is highly undesirable.

Beans.—The beans commonly used are the haricot, kidney, or French beans (*Phaseolus vulgaris*), and the broad or Windsor bean (*Vicia Faba*). The horse-bean is a variety of the latter. The broad bean is used generally in the fresh state, being grown in gardens, but is also dried and preserved. The haricot bean is a native of India. It is largely grown in Italy and France and was introduced into England in the sixteenth century. The scarlet-runner (*Phaseolus multiflorus*) is a variety of the same plant. It also is used as a green vegetable cooked in its pod. It is native to Mexico, and was introduced into England in 1633.

Haricot beans ought to be a much more popular food-stuff in Britain than they are. With rice or fatty food-stuffs such as bacon they make a well-proportioned and nourishing diet.

"For our labourer," says Sir Henry Thompson, "probably the best of the legumes is the haricot-bean, red or white, the dried mature bean of the plant whose pods we eat in the early green state as 'French beans.' For this purpose they may be treated thus: Soak, say, a quart of the dried haricots in cold water for about twelve hours, after which place them in a saucepan, with two quarts of cold water and a little salt, on the fire; when boiling remove to the corner and simmer slowly until the beans are tender; the time required being about two or three hours.[1] This quantity will fill a large dish, and may be eaten with salt and pepper. It will be greatly improved, at small cost, by the addition of a bit of butter, or of melted butter with parsley, or if an onion or two have been sliced and stewed with the haricots. A better dish still may be made by putting all or part after boiling into a shallow frying-pan, and lightly frying for a few minutes with a little lard and some sliced onions. With a few slices of bacon added, a comparatively luxurious and highly nutritive meal may be made. But there is still in the saucepan, after boiling the haricots, a residue of value, which the French peasant's wife, who turns everything to account, utilizes in a manner quite incomprehensible to the Englishwoman. The water in which dried haricots have stewed, and also that in which green French beans have been

[1] If the water is hard a little soda should be added to soften it.

boiled, contains a proportion of nutritive matter. The Frenchwoman preserves this liquor carefully, cuts and fries some onions, adds to it these and some thick slices of bread, a little salt and pepper, with a pot-herb or two from the corner of the garden, and thus serves hot. . . . But haricots are good enough to be welcome at any table. A roast leg or shoulder of mutton should be garnished by a pint, boiled as just directed, lying in the gravy of the dish; and some persons think that, with a good supply of the meat gravy, and a little salt and pepper, 'the haricots are by no means the worst part of the mutton.' Then with a smooth *purée* of mild onions, which have been previously sliced, fried brown, and stewed, served freely as sauce, our leg of mutton and haricots become the *gigot à la bretonne*, well known to all lovers of wholesome and savoury cookery. Next, white haricots, stewed until soft, made into a rather thick *purée*, delicately flavoured by adding a small portion of white *purée* of onions (not browned by frying as in the preceding sauce), produce an agreeable garnish for the centre of a dish of small cutlets, or an *entrée* of fowl. . . . Let me recall, at the close of these few hints about the haricot, the fact that there is no produce of the vegetable kingdom so nutritious; holding its own in this respect, as it well can, even against the beef and mutton of the animal kingdom. The haricot ranks just above lentils, which have been so much praised of late, and rightly, the haricot being also to most palates more agreeable. . . . I do not, of course, overlook in the dish of simple haricots the absence of savoury odours, proper to well-cooked meat; but nothing is easier than to combine one part of meat with two parts of haricots, adding vegetables and garden herbs, so as to produce a stew which shall be more nutritious, wholesome, and palatable, than a stew of all meat with vegetables and no haricots. Moreover, the cost of the latter will be more than double that of the former."

In China and Japan cheese is manufactured from a species of bean (*Soia hispida*). The beans are ground, made into a paste, and the vegetable casein is coagulated. It contains a little over 3 per cent of nutritive material.

Lentils (*Ervum Lens*) are extensively grown in Egypt, Algeria, Turkey, and the southern parts of Europe generally, and in the East. Esau's pottage is believed to have been made from the red or Arabian lentil, the finest variety. As sold in the shops the seeds are deprived of the husks and split. They also are highly nutritious, as the table shows.

Ervalenta and Revalenta Arabica are mixtures, according to Dr. Hassall, the former of the meal of the French or German lentil with a substance resembling Indian-corn meal, and the latter of the Arabian lentil and barley flour, with the addition of some saline material, chiefly salt. They are sold at a price ridiculously high considering the cost of their ingredients.

TUBERS AND ROOTS.

A tuber is an underground fleshy stem, often considered as a modification of the root. To the class of food-stuffs, tubers and roots, belong the potato, sweet-potato, yam, Jerusalem artichoke, turnip, carrot, beet-root, parsnip, radish, salsify.

The composition of the chief of these, mainly as given by Church, is shown in the following table:—

Average Percentage Composition of Potatoes, Carrots, Turnips, &c.

	Potato.	Sweet-potato.	Yam.	Jerusalem Artichoke.	White Turnip.	Carrot.	Beet-root	Parsnip.	Radish.
Water	75·7	74·0	78·6	80·0	92·8	89·0	82·2	82·0	93·34
Nitrogenous	2·3	1·5	2·2	2·0	0·5	0·5	0·4	1·2	1·23
Carbohydrate (Starch, Sugar, &c.)	19·7	20·2	16·3	14·4	4·0	5·0	13·4	8·7	3·79
Fat	0·3	—	0·5	0·5	0·1	0·2	0·1	1·5	0·15
Fibre	1·0	2·8	0·9	2·0	1·8	4·3	3·0	5·6	0·75
Saline	1·0	1·5	1·5	1·1	0·8	1·0	0·9	1·0	0·74

The large percentage of water in all these food-stuffs at once attracts one's notice, and is graphically shown in Plate IX. Turnip and carrot, in particular, have a very high percentage of water. Radishes resemble carrots in composition. In the next place it is noticeable that all of them are very deficient in flesh-forming and tissue-repairing material. The chief nutriment in them, possessed in greatest amount by the potato, is the carbohydrate ingredient, starch, &c. The proportion of saline ingredients, however, compares very favourably with that of grains.

Even the small amount of nitrogenous material is not all available as nutriment. A considerable proportion of it is found not to be of an albuminoid or proteid character. Thus the 2·3 per cent in the potato consists to some extent of substances belonging to the class of alkaloids, to which class such active principles as quinine, strychnine, etc., belong. Thus, in the potato there is one of them, namely, solanin, which, though nitrogen enters into its composition, is useless for nourishment. Of the carbohydrate element, while the larger proportion is starch, there is a small quantity of sugar, gum, and a substance called *pectin* or *pectose*, formed, like starch, of carbon, hydrogen, and oxygen, but in different proportions, found in most fruits and vegetables, and forming the basis of vegetable jellies. It is evident from the small total quantity of nutritive material contained in such vegetables as carrot, turnip, etc., that they are useful mainly on account of their flavour, and to some extent also because of their saline constituents, and ought to be considered only as agreeable additions to an otherwise plentiful diet.

Potato (*Solanum tuberosum*) belongs to the natural order *Solanaceæ*, the nightshade order, to which such very different plants as the deadly nightshade, tobacco, belladonna, stramonium, henbane, cayenne, and tomato belong. It is an enlargement of the underground stem, and the "eyes" are the buds of this part of the stem, capable of growing independently when detached from the rest. It is native in Chili, Peru, and Mexico, where it is found growing wild, whence it spread to North America. Brought to Europe by the Spaniards early in the sixteenth century, it was cultivated in gardens. In 1565 Sir John Hawkins introduced it into Ireland, and twenty years later Sir Francis Drake brought it to England. It failed to attract much attention, and a year later was reintroduced by Sir Walter Raleigh. It was many years, however, before it was cultivated to any extent, a century elapsing before it was grown in the open fields, and two centuries before it became popular. The name potato is derived from *batata*, the sweet-potato, with which it had been confounded, though the sweet-potato belongs to quite a different order. It grows well in all temperate climates, and it varies much in composition, according, among other things, to the soil on which it is reared.

In 1845 a disease broke out amongst it, dependent upon a fungus, the *Peronospora infestans*, which attacks the lower surface of the leaves and the stalks, having the appearance of brown patches. It appears in July, and penetrates to the tuber.

The substance of the potato is made up of compartments, filled with starch grains in an albuminous juice. In the deeper layer of the skin of the potato pigment is present, and here also the active principle solanin resides. This probably is the foundation for the popular notion that the water in which potatoes in their skins have been boiled is injurious, and ought to be thrown away. Dry heat, however, destroys the solanin, and it exists, in any case, in such small quantity as to be really too insignificant to be productive of any harm. Many people insist on potatoes being pared for a like reason, but they ought to be boiled "in their skins," as this helps to retain some of their valuable qualities. Salt added to the water in which they are boiled helps to prevent the loss of their saline constituents. These constituents are very valuable. Potash is the chief of them, existing to nearly 55 per cent of the total. There are present also some of the organic acids and notably citric. It is probably to the citric acid and potash salts that the potato owes its power for the prevention of scurvy. This power has been amply proved, though to which actual constituent it is due is not positively known. Cooking by steaming is, however, altogether the best way of preventing the loss of valuable ingredients.

Up to the date of the potato famine in Ireland that vegetable was the chief article of diet, an adult Irishman consuming, according to Smith, ten and a half pounds weight daily, three and a half pounds at each meal. For an example of its usefulness in affording a cheap diet see p. 623. As has been already indicated, it is not alone a suitable diet, because of its deficiency in albuminoid material. Beans or peas would supply that want, and butter-milk also. That would, of course, be done most effectually by beef or butcher's meat of some kind.

Starch is manufactured in large quantity from potatoes (see *British Arrow-root*, p. 586), and by permitting fermentation to occur spirit can also be produced, potato spirit, or fusel-oil (see p. 664), British brandy. By roasting, the starch is partly converted into dextrin, by which means British gum is obtained.

Sweet-potato (*Batatas edulis*) belongs to the *Convolvulus* order and is native to the Malayan Archipelago. It is largely cultivated in America, and also in Algeria and Southern Europe, and is grown in Spain and called the

Spanish potato. It was introduced into Spain before the common potato, and was brought to England by Drake and Hawkins, but has not been successfully cultivated, as it requires a warm climate. Its composition is nearly the same as that of the ordinary potato, but it contains 3 per cent of sugar, which the potato does not possess. It varies in size from 9 to 12 pounds in weight, and in Java is said even to attain to 50 pounds. It is a favourite and wholesome food and is said to possess slightly laxative properties.

Yam is also a tuber, belonging to a species of tropical climbing plants, of the genus *Dioscorea* (Fig. 201). Varieties of it are found in the West Indies (*D. sativa*), East Indies, South Sea

Fig. 201.—Yam (*Dioscorea globosa*).

Islands, New Zealand, and Japan and China. It cannot be successfully cultivated in England. It grows to a very large size, one tuber being sometimes 30 to 40 pounds in weight. It is not sweet like the sweet-potato, and its composition is very like that of the common potato (see table). Some species are said to possess poisonous properties.

Jerusalem Artichoke.—This plant belongs to the Sunflower tribe of the natural order *Compositæ*, and its technical name is *Helianthus tuberosus*. The Italian for sunflower is *girasole*, and it is said that in this case Jerusalem is a corruption of girasole. It is not much used in Britain, though it was cultivated in Europe before the potato, and was introduced into England from Brazil in 1617. It is a native of Mexico. The portion used as food consists of oval or rounded masses which form round the root. The carbohydrate of the artichoke consists chiefly of sugar, there is no starch, and consequently there is no mealiness produced on boiling as is the case with the potato.

Turnip.—The turnip as commonly used is the result of cultivation. The Swedish turnip sprang from a wild plant, the *Brassica campestris*, belonging to the natural order *Cruciferæ*. The wild plant has a spindle-shaped bitter root, little resembling the cultivated article. As the table shows it possesses little value as a food. It contains no starch, but a carbohydrate in the form of pectose, and very little albuminous material. A pungent essential oil is one of its ingredients. The **prairie turnip** of North America, which is much used as potatoes are elsewhere, has no relationship to the ordinary turnip. It is a tuber and belongs to the leguminous order of plants.

Carrots are also a product of cultivation, derived from the wild carrot (*Daucus Carota*), of the order *Umbelliferæ*, to which also celery, parsnip, and the poisonous hemlock belong. It grows abundantly in Britain, and is said to have been introduced during the Elizabethan period by the Flemish refugees who settled at Sandwich. The wild plant has a pungent odour and acrid disagreeable taste. Of the carbohydrate 4·5 per cent is sugar, the remainder is gum and pectose. The sugar can be removed in the shape of syrup, and submitted to fermentation to yield spirit. It is said that a substitute for coffee can be made from them, if they are first cut into pieces and roasted.

Parsnip (*Pastinaca sativa*). The parsnip belongs to the same order as the carrot, *Umbelliferæ*. It is a cultivated variety of a wild plant native to Britain. It contains about an equal percentage of sugar and starch, 3 of sugar, 3·5 of starch, the remaining carbohydrate being pectose. Spirit can also be prepared from it, as from carrot.

Beet-root.—There are several varieties of the beet. The common red beet is *Beta vulgaris*. There is the sea-beet (*B. maritima*), supposed to be the origin of the common form and of the sugar-beet, a white variety of *B. vulgaris*, and the field-beet or mangold-wurzel (*B. altissima*). They belong to the order of the goosefoots (*Chenopodiaceæ*). They are native to the south of Europe, and were introduced into Britain in 1656. Of the 13·4 per cent of carbohydrate 10 is sugar; and on this account the beet, especially the white variety, is grown extensively for the production of sugar and the distillation of alcohol. Thus the order of richness in sugar of carrots, parsnips, and beet-root is—

Parsnips, ...	3·0 per cent.
Carrot, ...	4·5 ,,
Beet-root, ...	10·0 ,,

Radish (*Raphanus sativus*) belongs to the natural order *Cruciferæ*, the same order which includes mustard and turnip. It is native to China, and has been cultivated in England since 1548. The roots are spindle-shaped or round like small turnips, and the exterior may be white, red, black, or violet, but the interior is always white. In composition it resembles the turnip, though it is less digestible, specially as it is usually eaten raw. The young leaves are used as a salad and the green pods as a pickle. The horse-radish (*Cochlearia Armoracia*), with a tap-shaped root, is employed in medicine because of the pungent acrid volatile oil, identical with oil of mustard, which it contains.

Salsify or **Purple Goat's-beard** (*Tragopogon porrifolius*) belongs to the order *Compositæ*. There are several varieties, the greater goat's-beard and the yellow, besides the purple. The name is due to the feathery appearance of the seeds. Salsify has a long tapering root, fleshy and tender, and yielding a milky juice. It is usually boiled or stewed, and has a sweetish taste like parsnip. It is also beat up with potatoes, after being boiled, and fried in small cakes, and from its taste when so cooked it is called the "oyster plant."

In Chili, Peru, and Bolivia there are several plants grown for their tubers, which are used for food, such as *Oxalis crenata*, *Oxalis tuberosa*, and which become mealy like potatoes on boiling. And there are many others of a like character in different parts of the world which are largely used as potatoes or yams.

HERBACEOUS ARTICLES.

Under this head are included the shoots, stalks, leaves, fruit, and seed of various plants, and sometimes the whole plants. The composition of some of the chief of them is shown in the following table:—

Average percentage Composition of Cabbage, Sea-kale, Lettuce, &c.

	Cabbage.	Sea-kale.	Savoy.	Cauliflower.	Spinach.	Lettuce.	Celery.	Water-cress.	Onion.	Asparagus.	Parsley.	Rhubarb.
Water	89·97	93·3	87·09	90·39	90·26	94·33	93·3	93·2	91·0	93·32	85·55	95·1
Nitrogenous	1·89	2·4	3·31	2·53	3·15	1·41	1·2	1·7	1·5	1·98	3·66	0·9
Carbohydrate (starch, sugar, &c.)	4·87	2·8	6·02	5·01	3·34	2·19	3·8	2·9	4·8	2·74	7·44	2·4
Fat	0·20	—	0·71	0·38	0·54	0·31	—	0·2	0·2	0·28	0·22	—
Fibre	1·84	0·9	1·23	0·87	0·77	0·73	0·9	0·7	2·0	1·14	1·45	1·1
Saline	1·23	0·6	1·64	0·82	1·94	1·03	0·8	1·3	0·5	0·54	1·68	0·5

It is convenient to group these numerous vegetables together, though they belong to widely different orders of plants, because the nutritive value of all of them is alike comparatively low, and, in the main, their value as food-stuffs depends upon the variety and flavour they impart to a meal, and also largely upon the salts and acid which they convey to the body. On this last account they are very useful in the prevention of scurvy. They are also distinguished from food-stuffs already considered in possessing chlorophyll, the green colouring matter of plants. Many of them possess also peculiar essential oils, usually of a pungent character, which confer upon them a peculiar flavour and sharpness. They all possess a very large proportion of water; and though many contain a larger proportion of nitrogenous material than potatoes and other vegetables already considered, they show a falling-off in the carbohydrate element. Of this element the large proportion in most of them is sugar. Thus in cabbage 2·29 of the 4·87 per cent is sugar; in celery 2·2 of the 3·8 per cent is sugar; in cauliflower the sugar is 1·27 per cent; in savoy, 1·29; in parsley, 0·75.

Cabbage belongs to the natural order *Cruciferæ*. The wild plant from which it sprang, the sea-cabbage (*Brassica oleracea*), grows upon the cliffs of the southern and western coasts of the British Isles. The term **colewort** is used as a general one to apply to all the plants of the genus. The final "wort" is the Saxon wyrt, a root, German wurz; while "cole" is the same as the Scotch "kale" or "kail," German "kohl," Saxon "caul." The ordinary white cabbage, savoy, Brussels sprouts, broccoli, cauliflower, and the red cabbage used for pickling, are all varieties of the original sea-cabbage—a small unimportant plant in comparison with its descendants. The cauliflower is the flower or inflorescence of the plant, developed by cultivation; Brussels sprouts are the buds which appear in the axils of the leaves, the angle between the leaf and the stem of the plant. The cabbage tribe is, as a rule, difficult of digestion, and in the bowels

sulphuretted hydrogen is apt to be formed from the abundance of sulphur they contain, thus occasioning offensive flatulence. The German sauerkraut is made from sliced cabbage, sprinkled with salt, pressed in tubs or barrels, and allowed to ferment till it becomes sour.

Sea-kale (*Crambe maritima*) is a hardy seashore plant, now grown in gardens and brought to great perfection, in which state it is said to be delicate and easy of digestion. By keeping the light from it, as is done with celery, it is kept white and an acrid taste prevented from developing.

Spinach (*Spinacia oleracea*) belongs to the same order as the beet (*Goosefoot* or *Chenopodiaceæ*). It is a native of Western Asia, and was introduced to England in the sixteenth century. The mountain spinach, a native of Tartary cultivated in France, belongs to the same tribe. It is the leaves of the plant that are used after being boiled, and sometimes as a salad.

Lettuce (*Lactuca sativa*) belongs to the *Compositæ*. It is a hardy plant, one of the chief vegetables used as salad because of its crispness and the quantity of water it contains, which makes it cool and refreshing. Such vegetables should be kept in water till used, as they absorb the water, remaining juicy and crisp instead of becoming dry. **Lactucarium or lettuce-opium,** is a drug obtained from the juice expressed from the flowering herbs of the garden and wild lettuce, and thickened by gentle heat. It possesses some slightly soothing properties, and is very occasionally given to induce sleep.

The **Endive** (*Cichorium Endivia*) belongs to the same order as the lettuce. It is a native of Northern China. It is the blanched leaves that are used, but it has a bitter taste.

Celery (*Apium graveolens*) belongs to the *Umbelliferous* order, native to Britain, growing wild in sandy marshes, and called **smallage.** The taste and smell of the wild plant are coarse and rank. By cultivation, however, by a method introduced from India, it becomes tender and pleasant. It is supplied with abundance of water and earthed up just to the tops of the leaves. It is used as a flavouring agent for soups and also as a salad. It contains a minute quantity of an essential oil, to which its peculiar aromatic properties are due.

Water-cress is a cruciferous plant, of which there are many varieties. The water-cress is *Nasturtium officinale*, the common garden-cress is *Lepidium sativum*. The water-cress is native to Britain, and grows in rivulets or shallow streams or ditches. Its pungent flavour is due to an essential oil. The common cress is a native of the East. Belonging to the same order is **white mustard** (*Sinapis alba*), whose leaves are also used as a small salad.

Onion and **Asparagus** both belong to the Lily order. The former (*Allium Cepa*) is a native of the Levant. The same species includes the shalot, leek, garlic, and chive. All of these possess a very strong pungent taste and smell, due to a volatile oil, rich in sulphur, which they contain in minute quantity. This oil confers a marked stimulating and irritating property on the plants. **Asparagus** (*Asparagus officinalis*), called vulgarly sparrow-grass, is originally a wild sea-coast plant, but is now grown in gardens. The part used is the young shoot, which constant cultivation has made delicate and tender. From the shoots a crystalline substance, asparagin or althein, can be separated. It is also found in the potato, in belladonna, in liquorice and marsh-mallow roots. It is used in some forms of dropsy and gout.

Parsley is an umbelliferous plant, the common kind (*Petroselinum sativum*) is a native of Sardinia. An essential oil with the peculiar aroma of the plant can be separated from it.

Artichoke, to be distinguished from Jerusalem Artichoke, is of the order *Compositæ*. It is the green flower-head of the plant (*Cynara Scolymus*), native to Barbary and South Europe. Another plant of the same genus, the **cardoon** (*C. Carduncellus*) is used on the Continent. The parts used are the thick, fleshy stalk and leaf-ribs. They are blanched for use. It is a native of countries on the Mediterranean shore.

Many other plants, in whole or part, are used as salad, &c., such as borage, sorrel, rape, dandelion leaves, and many others.

Rhubarb, though usually called a fruit, that is, the portion that is used for tarts, is really the fleshy leaf-stems of the plant. It belongs to the same natural order as buckwheat, the *Polygonaceæ*. It comes from the river Volga, whence it was brought in 1573. The root of the Turkey rhubarb is used as medicine. *Rheum* is the name of the plant, the English rhubarb being *R. rhaponticum*, the medicinal kind being *R. officinale*. Formerly the leaves were boiled to yield a sauce used for meat. As a nutrient it is of little value, but its juice and mineral matter are valuable. The quantity of sugar it contains (2 per cent) enables a home-made wine to be manufactured from it.

FRUITS.

Average percentage Composition of Cucumber, Vegetable Marrow, and Tomato.

	Cucumber.	Vegetable Marrow.	Tomato.
Water	96·2	94·8	89·8
Nitrogenous	0·2	0·6	1·4
Carbohydrate (starch, sugar, &c.)	2·7	2·6	6·7
Fat	—	0·2	—
Fibre	0·5	1·3	1·3
Saline	0·4	0·5	0·8

These three fruits have been placed together because they are used rather as vegetables than as fruits in the ordinary sense of the word. They are, however, the fruits of their respective plants.

Cucumber belongs to the natural order *Cucurbitaceæ* (*Cucurbita*, Latin, a gourd), to which also belong the gourd, the pumpkin, the melon, and of medicinal plants the colocynth (bitter-apple or bitter-cucumber) and bryony. The common cucumber is the *Cucumis sativus;* it is native to the Levant, and was introduced into England in 1573. They flourish best in rich, open soil, need plenty of water, and are more juicy and digestible when grown quickly under glass. They are, however, in any form rather difficult of digestion, and are specially so when raw. The addition of vinegar, pepper, &c., aid digestion by stimulating the stomach. They are really of no nutritive value, consisting mainly of water, as the table shows; the only nutrient is 2 per cent of sugar. When young, cucumbers are pickled under the name of gherkins.

Vegetable Marrow is akin to the pumpkin and common gourd, belonging to the same order as they and cucumber. It is *Cucurbita ovifera.* The **Squash** is a variety of the same plant. It contains less water and more nutrient than cucumber. Of the 2·6 per cent of carbohydrate, 2 is sugar and ·6 starch. It is a wholesome adjunct to food.

Melon (*Cucumis Melo*) is a variety of the gourd. The water-melon (*Citrullus vulgaris*) is another variety.

Tomato (*Lycopersicum esculentum*, love-apple) belongs to the Nightshade order (*Solanaceæ*), as does the potato and tobacco. It is a native of South America. In Britain they grow best in hothouses. They are used in all sorts of ways, cooked in sauces, or raw, with the addition of pepper and salt, or in their natural fully ripe state without any adjunct. They have a very agreeable flavour, and are readily digestible. They contain ·7 per cent of a free acid—malic acid—the same as exists in the apple, pear, and plum.

Egg-apple (Fig. 202) (a variety of *Solanum esculentum*) is used for sauces, or boiled, and otherwise used as the tomato. It is the fruit of the plant to which the term egg-apple, aubergine, or brinjal is applied. "It is of an elongated form and purple colour. It is somewhat largely eaten on the Continent, and to some extent also in England; but it is dry and spongy, and devoid of the agreeable qualities belonging to the tomato. In America it is a favourite vegetable, and is there usually sliced and fried."

Fig. 202.—Egg-apple.

Average percentage Composition of Apples, Pears, Plums, Grapes, &c.

	Apples.	Pears.	Plums.	Damsons.	Peach.	Cherries.	Grapes.	Gooseberries.	Currants.	Strawberries.	Oranges.

Saline	0·4	0·3	0·6	0·7	0·6	0·7	0·4	0·5	0·7	0·8	0·5

[1] Malic acid. [2] Tartaric acid. [3] Citric acid. [4] A mixture of citric and malic acids.

The fruits in the above list have all very much the same characters, so far as chemical composition is concerned. In all of them there is a very low proportion of nitrogenous constituent, but a considerable quantity of carbohydrates, especially sugar, and other non-nitro-

genous substances such as gum and pectin, the jelly-like material obtainable from fruits. The quantity of sugar varies with the degree of ripeness. In the unripe condition starch rather than sugar is present, but by process of ripening the starch becomes transformed. At the same time much of the acid and astringent constituents of the unripe fruit disappears. It is during this process that the special flavour is developed, the transformation being the result of the absorption of oxygen, which is characteristic of ripening fruit. When the fruit is overripe, fermentive changes have set in, and changes of decomposition, by which the fleshy part of the fruit is broken down, and the seed which it shelters liberated. Besides, for the sugar, &c., which they contain, fruits are valuable for their free acid, which varies in different fruits, being malic, citric, tartaric, or a mixture of some of them (see foot-notes), and also for their saline ingredients. These vegetable acids and salts are specially serviceable when salted or preserved meats are largely used in the diet, as they supply ingredients that without them would be wanting, and whose absence would occasion a very unhealthy condition, scurvy being apt to arise. They are useful also in correcting the tendency to the accumulation of excessive quantity of acid in the body, especially uric acid, of which gout, and probably to some extent also rheumatism are manifestations. Taken freely, these substances diminish the acidity of the urine, and, if taken in larger quantities, render it alkaline. A diet rich in animal food is apt to occasion unsatisfactory states of general health, because of the excessive storing of acid in the system. There is little doubt that the advantage experienced by many from a more free use of fruits than is customary is due to their power to diminish this acidity. Some forms of headache, especially the sick or nervous headache, megrim, are supposed to be partly caused by such excessive accumulation of acid in the system. It would be worth while for those, subject to complaints of this kind, to try the effect of free use of such fruits as oranges, lemons, and tomatoes.

Apples, Pears, Quinces, and **Medlars** all belong to the sub-order *Pomeæ* of the natural order of the rose (*Rosaceæ*). The apple-tree is called *Pyrus Malus;* the pear is *Pyrus communis.* The varieties of cultivated apples have sprung from the wild, or crab-apple of the hedges, a native of Great Britain. It grows in all temperate climates. Normandy pippins, or "biffins," are apples dried and flattened. **Cider** is the fermented juice of apples, **verjuice** of the crab-apple, and **perry** of the pear. Apples seem not to be so difficult of digestion, when raw, as is generally supposed, if they are well chewed. Stewed or roasted, they are still more easy of digestion. They are useful in persons troubled with habitual costiveness of bowels.

Fig. 203.—Sour-sop or Anona (*Anona muricata*).

The term apple is applied to other fruits of quite different kinds. Thus the **custard-apple** is the fruit of the *Anona reticulata*, of the same tribe as the sour-sop of the West and East Indies. (See fig. 203.) The **egg-apple** belongs to the same order as the tomato, and is used as a vegetable (see p. 574).

The **Quince** is the fruit of *Pyrus Cydonia*, or *Cydonia vulgaris.* It is supposed to be a native of Western Asia. The fruit is golden yellow. In temperate climates, because of its want of ripening, it is used cooked in sugar, or made into marmalade. The Bengal Quince, *Ægle Marmelos,* golden apple, or bael fruit belongs to the orange order.

Fig. 204.—Quince (*Cydonia vulgaris*).

The **Medlar** is the fruit of the tree *Mespilus germanica,* which grows wild in several parts of Central Europe and in Britain. The pulp is very tough, but becomes soft when decay has set in, in which condition the flavour is deemed best.

Fig. 205.—Peach (*Amygdalus persica*).

Plums, Damsons, Apricots, Peaches, and **Cherries** all belong to the *drupaceous* or stoned-fruit class of the Rose order. The common plum

is *Prunus domestica*, which is a native of Asia Minor. There are various species belonging to different temperate climates. The damson is a plum originally derived from Damascus, and the green-gage is another variety. **Apricots** are the fruit of *Prunus armeniaca*. **Cherries** are the fruit of *P. Cerasus*. Their richness in sugar is a notable feature. **Kirschwasser** is a liqueur obtained from them. **Maraschino** is another liqueur prepared from a more delicately-flavoured kind. Prunes, or French plums, are dried plums, the finest being called by the latter name. The **peach** belongs to the genus *Amygdalus*, the *A. persica*, the almond group of *Rosaceæ*. The composition given in the table does not include the stones. It will be seen that their nutritive value is insignificant. **Nectarines** are a variety of the same tree.

Grapes. The grape is the fruit of *Vitis vinifera*, of the natural order *Vitaceæ*, native to the East, about the region south of the Caspian. There are a great many varieties. Raisins are the dried fruit, and currants are small varieties. **Sultanas** are raisins without stones; **muscatels** are the finest sort, dried in the sun on the branch, after the stalk is partially cut through. The large percentage of sugar contained in grapes gives them a pre-eminence as regards nutritive quality above every other fruit of the berry kind. Raisins contain 45 per cent less water than grapes, a total of only 32 per cent, and they contain no less than 55 per cent of sugar, so that they are highly nourishing, though the nitrogenous element amounts to only 2·4 per cent. The value of associating almonds and raisins is seen from the fact that the former contains 24 per cent of nitrogenous material and nearly 54 per cent of fat, they are, that is to say, very rich in exactly the ingredients in which raisins are deficient. The acid of the grape is chiefly tartaric, and it is usually combined with potash to form tartrate of potash.

"I think we may assert," says Dr. Cullen, "that grapes, which contain a large quantity of sugar, are, if taken without their husks, the safest and most nutritive of summer fruits." "In the inflammatory form of dyspepsia, and in pulmonary affections, ripe grapes are eaten, in considerable quantities, in Switzerland and other parts of the Continent, occasionally with considerable benefit, and forming what is called the 'cure de Raisins'" (Pereira). They act both upon the bowels and kidneys, gently stimulating the action of both, specially if taken in the morning on an empty stomach.

Strawberries are natives of temperate climates, and are found in Europe, America, and Asia. They belong to the Rose order, to the genus *Fragaria*, the common strawberry being *F. vesca*. The English strawberry has reached its present condition as the result of cultivation. They are not rich in nutritive material, but if eaten alone, or only with sugar, they are digested with comparative ease.

Currants and **Gooseberries** belong to the tribe *Grossulaceæ*, of the natural order *Saxifragaceæ*. The currant plant is *Ribes*, the red currant being *R. rubrum*, and the black *R. nigrum*, while the gooseberry is *R. grossularia*. The latter is native to many parts of Europe and Northern Asia. The currants are also natives of Europe and Asia and some parts of North America. Both currants and gooseberries are alike in alimentary properties, which are of little consequence. These currants are to be distinguished from the dried currants, which are small black dried grapes.

Raspberries and **Blackberries** (brambles) belong to the sub-order *Roseæ* of the natural order *Rosaceæ*. The former (*Rubus idæus*) is a native of Britain; the latter (*Rubus fruticosus*) is also indigenous in Britain and Europe generally. It is a hedge bramble. The **Dewberry**, or grey bramble (*R. cæsius*), does not grow in hedges but on the ground.

Bilberries or **blaeberries** (Fig. 206) (*Vaccinium myrtillus*), **bog whortleberry** (*V. uliginosum*), **red whortleberry** or **cowberry** (*V. vitis idæa*), **marsh whortleberry** or **cranberry** (*V. oxycoccus*), all belong to the natural

Fig. 206.—Bilberry.

Fig. 207.—Barberry (*Berberis vulgaris*).

order *Vacciniaceæ*. They are found in Britain, Europe, and America. They are all very much alike in chemical composition.

Barberry (Fig. 207) (*Berberis vulgaris*) belongs to the order *Berberidaceæ*. It is very acid and astringent, found in Europe, Asia, and America, in hedges. Pepperidge or peprage bush is an old name in England for the plant. The berries are oval in form, and generally

bright red. A mordant for dyers is made from the bark.

Elder-berries are the fruit of *Sambucus nigra,* small trees or shrubs of the natural order *Caprifoliaceæ.* The honeysuckle and viburnum belong to the same order. It is native to Europe and the north of Asia and Africa. The branches of the tree contain an unusually large amount of pith, which is easily removed, so that tubes are readily formed. Hence the name bore-tree, and in Scotland bour-tree. Elderberry wine is a highly-flavoured wine made from the berries, which are black in colour and faintly acid to taste. Elder-rob is the juice obtained by pressing the berries.

Mulberries (Fig. 208) are the fruit of the *Morus nigra,* of the order *Urticaceæ,* or *Moraceæ,* the same order to which fig belongs. It is a native of Persia, but is extensively grown in Europe. The fruit is purplish-black, more than usually acid, and with a fine flavour. It is cooling and slightly laxative.

Fig. 208.—Black Mulberry (*Morus nigra*).

Oranges are the fruit of the *Citrus,* belonging to the natural order *Aurantiaceæ.* The sweet orange is *C. Aurantium* (Fig. 209). It is supposed to be native to India and China, but has long been grown in Egypt, Italy, Spain, and other parts of Southern Europe. It is in perfection only when gathered ripe from the tree. The imported oranges are all pulled while yet unripe. The nutrients it contains are too small in quantity to make the fruit valuable from that point of view, but the acid it contains, and the salts, and the essential oil of the rind, confer upon the fruit a very high value, and make them exceedingly valuable and wholesome food adjuncts. When quite ripe it may be partaken of in almost any state of health, the pulp being, of course, rejected after the juice has been sucked out. The acid is citric acid, and it is united in the fruit with potash, chiefly as citrate of potash. There are several varieties of the orange. The bitter or Seville orange is *C. vulgaris.* The rind is rich in flavouring oil, and is largely used for flavouring, and for the extraction of tincture, to be employed as an aromatic tonic. The flavour of the liqueur curaçoa is due to the bitter orange. From the flower of this variety, also, the finest orange-flower water is distilled. From orange-flowers another oil is obtained—the oil of neroli. The mandarin orange is a variety of the sweet orange. So also is the Malta orange with its blood-red flesh. The **Citron** (*C. Medica*) is a different species. The **Lime** (*C. acida*) is native to the East, and is grown in the West Indies and south of Europe. It is smaller than the lemon. Its juice is very acid, and is extensively used as a preventive of scurvy. The **Sweet Lime** (*C. Limetta*) is a variety.

Fig. 209.—Orange (*Citrus Aurantium*). *a*, Ovary. *b*, Style. *c*, Stamens. *d*, Petal. *e*, Section of fruit.

The **Lemon** (*C. Limonum*) is a native of the north of India, but is grown also in Southern Europe. The juice is more acid than that of orange, and is very extensively used for a refreshing beverage, the essential oil from the rind being also a popular flavouring agent.

The **Shaddock** (*C. decumana*) and the **Pomelo** or **Pompelo** (*C. Pompelmoos*) very much resemble one another and the orange. The latter is the fruit sometimes called "the forbidden fruit."

The **Cumquat** (*C. japonica*) is another species of *Citrus.* All these varieties have the same general characteristics of juicy acid fruits and aromatic oils in the rind.

The **Pomegranate** (Fig. 210), fruit of the *Punica granatum,* is not unlike the orange. The pulp is reddish, slightly acid. The rind is very astringent, and is used sometimes on this account. The root has the same action, and is used in medicine; the dried root is used for yielding an astringent decoction. The *Punica granatum,* however, does not belong to the same order as the orange, but to the order *Myrtaceæ,* to which cloves, all-spice, cajeput, and the blue-gum tree belong. **Guava** (*Psidium pyriferum*) also belongs to the same order as pomegranate. It yields the well-known West Indian preserve, guava-jelly. Guava preserves are also

Fig. 210.—Pomegranate (*Punica granatum*).

largely made at the Cape Colony. It is a roundish fruit, larger than a hen's egg, with smooth yellow rind, and firm flesh-coloured pulp, filled with hard seeds, of sweetish aromatic taste. There are several varieties of it—red guava and China guava, which are more acidulous to taste than the common or white variety.

Average Percentage Composition of Figs, Dates, and Bananas and Bread-fruit.

	Dried Turkey Figs.	Dates (stoned).	Bananas (peeled).	Bread-fruit.
Water	17·5	20·8	73·9	63
Nitrogenous	6·1	6·6	4·8	3
Carbohydrate (starch, sugar, &c.)	65·9	65·3	19·7	14
Fat	0·9	0·2	0·6	
Fibre	7·3	5·5	0·2	20
Saline	2·3	1·6	0·8	

These fruits occupy a very different position from those of the preceding table, dependent upon their great alimentary value. Rich in starch or sugar, and with a proportion of albumin and a very small percentage of fat they are, each of them, capable without further addition, except that of water, of sustaining life for prolonged periods. Though generally regarded simply as pleasant fruits, in the ordinary meaning of that word, they form in some parts of the East the main food of the people for certain seasons.

Figs are the fruit of the *Ficus carica* (Fig. 211), belonging to the natural order *Moracœe*, to which the mulberry and banyan belong, and to which the india-rubber tree (*F. elastica*) of commerce belongs. It is grown in warm climates, native to the East and naturalized in Southern Europe, attaining its perfection along

Fig. 211.—Fig (*Ficus carica*).

Fig. 212.—Sycamore (*Ficus sycomorus*).

the Mediterranean shores, and in Turkey. The fig as eaten is really a hollow fleshy receptacle for the fruits, which are concealed within it. In the ripe state the so-called seeds are the actual fruits, the ripe carpels or seed-vessels of the flowers. Of the fig there are numerous varieties, differing in size, colour, &c. The **sycamore** (*Ficus sycomorus*, Fig. 212) is a species of fig. Its fruit is also eaten and is sweet and delicate; it is smaller than the ordinary fig.

The table shows the composition of the finest dried figs. The carbohydrate is mainly sugar, to the extent of $57\frac{1}{2}$ of the 65·9 per cent. By referring to p. 562 it will be seen that they contain almost as much nitrogenous material as fine white bread, and over 13 per cent more carbohydrate and more fat. One may, therefore, say they contain more nutriment than bread, but the so-called seeds are liable to cause irritation of the bowel if they are eaten in large quantity. One of the finest figs steeped over night in a quantity of water such that it can absorb, and eaten in the morning on rising, is a gentle aid to relaxation of the bowels.

The **Banyan** (*Ficus indica*) belongs to the same order as the fig, and produces edible fruit

Fig. 213.—Banyan Tree.

of the size of a cherry. It is a tree remarkable for size, owing to its manner of growth. The branches send down shoots which take root and grow into trunks, and thus the tree spreads till it covers a large area. A famous tree on the banks of the Ner budda has 350 such stems, each of the size of an ordinary trunk, and 3000 smaller ones. It can shelter beneath it 7000 men (Fig. 213).

Fig. 214.—Prickly-pear.

Indian-fig or **Prickly-pear** (Fig. 214) (*Opuntia vulgaris*) does not belong to the fig or pear order, but to the Cactus order (*Cactaceæ*). It is a native of America, and is grown in Southern Europe and North Africa. The fruit resembles a fig of a deep rose colour, larger than a hen's egg, with juicy and sweetish acid pulp.

Dates are the fruit of the date-palm (Fig. 215)—the palm-tree of Scripture (*Phœnix dacty-*

lifera). It is a native of the north of Africa and parts of Asia, and has been brought to Southern Europe. Its stem passes straight up without branch or interruption to a height of 50 or 60 feet, and then throws out a crown of feather-shaped leaves. The fruit is in bunches of 180 to 200 dates, each bunch weighing 20 to 25 pounds. The fruit is eaten in the fresh ripe state, or dried, and also pounded or pressed into a kind of cake, for the use of travellers through the desert, and the inhabitants of Northern Africa. The table shows the composition of the date as imported and after being stoned. In this condition it is in chemical composition much like the fig. The date-palm "is invaluable amid parched sands and arid deserts. Wherever a spring of water appears amid the sandy deserts of Africa, this graceful palm yields at once both its grateful shelter and its nourishing fruit. Where all other crops fail from drought the date-tree still flourishes. In Egypt and Arabia it forms a large portion of the general food, and among the oases of Fezzan 'nineteen-twentieths of the population live upon it for nine months of the year'" (Johnston).

Fig. 215.—Date-palm (*Phœnix dactylifera*).

Banana is the fruit of a favourite tropical tree (*Musa sapientum*, Fig. 216) of the natural order *Musaceæ*. The leaves are 6 feet long by 1 broad, and are used for thatching, basket-making, &c., while the quantity of fibrous tissue in the stalks makes them useful for the production of flax. Manilla hemp is yielded by a tree of the same order (*M. textilis*). The fruit grows in bunches of from 100 to 200, weighing 40 to 80 pounds. Its main constituent is, in the unripe state, starch, which in process of ripening becomes converted into sugar. Of very luscious taste it is a wholesome and nutritious food. The tree yields, for the same extent of ground covered, more food than any other vegetable. According to Humboldt 1000 square feet of ground will yield of potatoes 462 pounds, of wheat 38 pounds, and of bananas 4000 pounds, and in a shorter period of time. "About $6\frac{1}{2}$ pounds of the fruit, or 2 pounds of the dry meal, with $\frac{1}{4}$ pound of salt meat or fish, form, in tropical America, the daily allowance for a labourer, whether slave or free." The unripe fruit keeps better than the ripe, because of the carbohydrate being yet starch, and when dried in this state forms a kind of bread. Meal is prepared by pounding and sifting the dried fruit.

Fig. 216.—Banana (*Musa sapientum*).

The **Plantain** (Fig. 217, *Musa paradisiaca*), a variety of the same plant as the banana, yields a fruit almost identical with it, and equally useful. In British Guiana the meal, obtained by drying and pounding the fruit, is largely used for children and invalids.

Fig. 217.—Plantain-tree (*Musa paradisiaca*).

Fig. 218.—Bread-fruit (*Artocarpus incisa*).

Bread-fruit (Fig. 218) is obtained from a tree (*Artocarpus incisa*) found in the islands of the Pacific, specially in the Friendly and Marquesas Islands. The fruit is round and about the size of a child's head, being formed of the female flowers united into a fleshy mass. Several crops appear in succession, the tree flowering for eight or nine months continuously. Like the banana its chief ingredient is carbohydrate, which becomes sugar when the fruit is fully ripe, but is in the form of starch when unripe. Raw, the fruit is insipid in taste, and it is, therefore, usually plucked before being ripe; the rind is removed and the white pith is wrapped in leaves and baked on hot stones. "In this state it tastes like white wheaten

bread, sometimes rather sweeter." During the months when the tree is not bearing, the unripe fruit is used in a preserved state. The preservation is effected in paved pits covered with leaves and stones, where the fruit becomes sourish and forms a kind of paste, of which a piece is baked on stones as required. In this form it is said to taste like black Westphalian bread when not thoroughly baked. These trees, it is said, will yield fruit sufficient to sustain one man for eight months. "Whoever has planted ten bread-fruit trees has fulfilled his duty to his own and succeeding generations as completely and amply as an inhabitant of our rude clime, who, throughout his whole life, has ploughed during the rigour of winter, reaped in the heat of summer, and not only provided his present household with bread, but painfully saved some money for his children" (Captain Cook).

A variety of the bread-bruit is **Jack-fruit**, yielded by the *Artocarpus integrifolia.* The tree is grown in Southern India and in Asia, and the fruit is much used in Ceylon. It is coarser than the bread-fruit.

NUTS.

Average percentage Composition of Nuts.

	Almonds.	Filberts.	Walnuts.	Cocoa-nuts.	Pea-nuts or ground-nuts.	Chestnuts.
Water	5·4	4·1	4·7	46·6	7·5	51·5
Nitrogenous	24·2	15·6	16·4	5·5	24·5	5·5
Starch, gum, &c.	7·2	9·0	7·9	8·1	11·7	38·3
Fat	53·7	66·1	62·9	35·9	50·0	1·4
Fibre	6·5	3·3	6·1	2·9	4·5	1·6
Saline	3·0	1·9	2·0	1·0	1·8	1·7

The prevailing characteristic of nuts is well shown in the above table. They are all rich in oil, exceptionally rich indeed, with the exception of the chestnut. The proportion of oil, scarcely below 50 per cent in any, gives them a very high alimentary value. At the same time they are also rich in albuminoid material, on an average as rich in that ingredient as flesh meat. They contain comparatively little starch. In fact the starch of the cereals is in the nuts replaced by oil. Although thus a very nourishing food they are rather difficult of digestion, unless when ground and mixed with some lighter kind of food, which will keep the nut in a finely-divided state. The fat is apt under exposure to become somewhat rancid. The chestnut is quite an exception to these general rules. It is a farinaceous seed, the starch taking the place of oil in quantity, and it is much less rich in nitrogenous material, resembling, therefore, the cereals.

Almond is the seed of the *Amygdalus communis* (Fig. 219), belonging to the natural order *Rosaceæ.* It belongs to the East, and is extensively cultivated in the south of Europe. The bitter almond (*A. amara*) is a variety of the former. The sweet almonds imported from Malaga, and called Jordan almonds, are the finest. By pressure the oil may be separated from the nut, the ordinary almond-oil of commerce, consisting chiefly of olein, which is bland, harmless, and odourless. From bitter almonds, by distillation, a volatile oil may be separated, which is of a different character. As sold in the shops it contains prussic acid, and is highly poisonous. This poisonous property is due to the presence of hydrocyanic or prussic acid, which, however, does not exist in the seed as such, but is produced as a result of a fermentation set up when the seed is moistened. This fermentation is due to the action of two substances contained in the seed, emulsin, an albuminous substance, and amygdalin, a crystalline nitrogenous substance. The result of the interaction of these two substances is the production of the volatile oil (essential oil of bitter almonds), prussic acid, and other substances. The prussic acid may be driven off from the oil by heat, and then the oil is harmless. But this is not usually done, and the oil retains its poisonous character. This fermentive change may occur in the mouth on chewing the bitter almond, and risk consequently attends their being eaten. Pereira says "the smaller animals, as dogs, pigeons, &c., are readily destroyed by them. One drachm (60 grains) has killed a pigeon, and twenty seeds have destroyed a dog. . . . . Macaroons

Fig. 219.—Almond (*Amygdalus communis*).

and ratafia cakes, as well as noyau, which owe their peculiar flavour to these seeds, likewise prove injurious when taken in large quantities." The essence of bitter almonds, sold for flavouring purposes, is the essential oil diluted with spirit. It should not be freely employed.

Sweet almonds are apt to occasion very considerable digestive disturbance, if eaten without the skin being removed, that is unblanched. Almonds thus eaten have been known to produce sickness, swelling of the face, and nettle-rash. The favourite sweetmeat marzipan is a sweetened almond paste.

Filbert Nuts, Hazel-nuts, and **Cob-nuts** are all produced from varieties of the same plant, *Corylus*, natural order *Corylaceæ*, to which the oak, beech, and sweet chestnut belong. **Hazel-nuts** are derived from *C. avellana*, which grows wild in Great Britain; the best come from Spain, and are called Barcelona nuts. The **filbert** (*Corylus tubulosa*) is a carefully-cultivated variety, and to it the remarks made at the beginning of these paragraphs fully apply.

Walnuts are the seeds of a tree, *Juglans regia* (Fig. 220), of the order *Juglandaceæ*. It is a tall spreading tree, a native of Persia, and was introduced into Greece and Italy some centuries before the Christian era. A sweet oil, used for food and, under the name of nut-oil, as a drying oil for painting, may be expressed from them. Unripe, they are used for pickling and making ketchup. The **butter-nut** from *Juglans cinerea*, and the black walnut are varieties much cultivated in America. The hickory tree (*Carya alba*) yields a nut, the **hickory-nut**, and belongs to the same natural order. A variety of it, *Carya olivæformis*, yields the **pecan-nut**. These are all North American trees.

Fig. 220.—Walnut-tree (*Juglans regia*).

Cocoa-nut is the fruit of a palm, Fig. 221 (*Cocos nucifera*), belonging to the natural order *Palmaceæ*. The name is said to be derived from *coco*, meaning a distorted mask, the name given to the nut by the Portuguese in India, because of the markings at the base of the nut suggesting a monkey face. The tree is grown extensively in the tropics. The fruit is in bunches of 12 to 20, and a single tree will bear from 80 to 100 nuts. Every part of the tree is useful. A thick fibrous husk surrounds the shell, of which matting is made, as well as a yarn called **coir**, of which cordage may be made; the shell itself is used for bottles and drinking-cups, and if burnt yields valuable charcoal. From the flowering branch is obtained a sweet juice, which, when allowed to ferment, is called **toddy** or **palm-wine**, and from this the spirit called **arrack** is distilled. The table shows the richness of the nut in oil, which may be separated out by pressure. The edible portion is somewhat fibrous and indigestible. The nut, however, is the chief food of the inhabitants of Ceylon, the South Sea Islands, and other tropical regions. The milk of the cocoa-nut is pleasant and cooling, and has the following composition:—

Fig. 221.—Cocoa-nut Palm (*Cocos nucifera*).

Water	91·5
Nitrogenous	·46
Fat	·07
Sugar, &c.	6·78
Saline	1·19

The Ground-nut or **Pea-nut** (Fig. 222) is the fruit of a leguminous plant, the *Arachis hypogæa*, common to the warm parts of America. It is also cultivated along the West Coast of Africa. It flowers not unlike the pea. The seeds are in pods, borne on long stalks, which, after flowering is past, curl towards the ground, so that the pods become buried in the earth, where they come to maturity. They contain 50 per cent of oil, and when this has been removed by pressure, the cake that is left, rich in albuminous material and starch, is used for feeding cattle.

Fig. 222.—Ground-nut (*Arachis hypogæa*).

Pistachio-nuts, the fruit of a small tree, the *Pistacia vera* (Fig. 223), is native to Western

Asia, but cultivated along the Mediterranean coasts. To the same order belong the sumach, mango, and cashew. Mastic is the product of one of the pistacias (*P. lentiscus*). The fruit is like a small almond, and has a similar taste. The kernel contains chlorophyll, which gives it

Fig. 223.—Pistacia vera.

Fig. 224.—Anacardium occidentale. 1 1 1, Cashew-nuts.

a green colour. It is sometimes called the green almond. They are used for confectionery and dessert. Their composition is almost identical with that of the ground-nut (see table).

Cashew-nuts or **Acajou-nuts** (Fig. 224) are the fruit of the *Anacardium occidentale*, of the same order as the pistacia. It is a native of the West Indies. The nut is kidney-shaped, and about an inch long. The shell is very hard, and between its outer and inner layer there is a black acrid juice, which is driven off in very acrid fumes when the shell is roasted. The kernel contains a pleasant, wholesome oil, and is a common article of food in the tropics. The stalk of the fruit is large and fleshy, and may be eaten.

Brazil-nuts are the seeds of the juvia tree, *Bertholletia excelsa* (Fig. 225), belonging to the order *Lecythidaceæ*, which grow in abundance in Guiana, Venezuela, and in Brazil. The fruit consists of an outer hard shell, about ½ inch thick and 6 inches in diameter. Within it there are four compartments, each containing six or eight triangular nuts very closely packed. The kernel is rich in oil.

Fig. 225.—Fruit of *Bertholletia excelsa*.

Chilian Pine or **Puzzle-monkey** is a pine whose seeds are much used for food. The tree, *Araucaria imbricata*, is one of the *Coniferæ*, found in South America, Australia, and Pacific Islands. It is a favourite lawn tree in Britain. In Chili and Patagonia its seeds are used for food, and it is said "the fruit of one large tree will maintain eighteen persons for a year."

Dika Bread is made from the fruit of the *Irvingia Barteri* or *wild mango*, though it is not related to the Indian mango. It belongs to the order *Simarubaceæ*, to which quassia belongs. The tree grows on the West Coast of Africa. The fruit "is about the size of a swan's egg. It contains a large white almond-shaped kernel. The bruised kernels, warmed and pressed, form the so-called dika bread, which is largely consumed by the natives of the Gaboon, who use it when scraped or grated in stews" (Church). It consists to the extent nearly of three-fourths of fat, as the following note of its composition shows:—

Water	5·0
Nitrogenous	9·5
Starch	7·2
Fat	73·0
Fibre	3·0
Saline	2·3 (Church).

Chestnut.—The Spanish or sweet chestnut is the produce of a stately tree, the *Castanea vesca*, which is a native of Western Asia, and is largely cultivated in Southern Europe and in North America. It belongs to the natural order *Corylaceæ*, also called *Cupuliferæ*, to which also the oak, beech, and hazel belong. It is eaten raw or roasted; it is also ground into flour and made into bread, which is readily done, because of the large quantity of starch it contains and the minute quantity of fat. It is an important article of food in Southern Europe, of agreeable flavour, but somewhat difficult of digestion.

Fig. 226.—Chestnut (*Castanea vesca*).

FUNGI.

Average percentage Composition of Mushrooms, &c.

	Mushroom.	Morel.	Truffles. White.	Truffles. Black.
Water	90·0	90·0	72·4	72·0
Nitrogenous	5·0	4·4	9·9	8·8
Carbohydrates	3·8	3·7	15·2	16·6
Fat	0·7	0·6	0·4	0·6
Saline	0·5	1·3	2·1	2·0

Fungi are plants of a simple type of organization. They contain no chlorophyll, that is the green colouring matter of plants. They possess a considerable quantity of nitrogenous material, and are, therefore, of considerable alimentary value, but they are used mainly as flavouring and seasoning agents and for the production of sauces.

Mushroom.—There are many varieties of mushroom, some of them suitable for eating, many of them poisonous. It is said, also, that under circumstances of situation a mushroom, usually employed for food, may become hurtful. The species commonly used is the *Agaricus campestris*, or field mushroom. It is found growing in the open field in August and the two following months. It may be cultivated in gardens all the year round. They are eaten raw, boiled, baked, stewed or pickled, and when salted and pressed they yield ketchup. The mushroom consists of a net-work of thread-like material, the mycelium, growing underground. From this the stalk springs, bearing the head or cap or pileus of the mushroom. This is often of a sort of umbrella shape, and upon its under surface is a series of gills or bars, which bear the spores or seed of the fungus.

It is difficult to distinguish between good and poisonous mushrooms. As a rule, those suitable for food are white or brownish; the gaudily coloured are poisonous. The suitable kinds are found growing in the open fields, not in damp, shady places. Bentley gives the characters as follows:—

Mushrooms suitable for eating:

1. Grow solitarily in dry airy places.
2. Are generally white or brownish.
3. Have a compact brittle flesh.
4. When cut do not change colour by the action of the air.
5. Have a watery juice.
6. Their odour is agreeable.
7. Their taste is neither bitter, acrid, salt, nor astringent.

Poisonous mushrooms:

1. Grow in clusters in woods, and damp, dark places.
2. Are usually of a bright colour.
3. Have a tough, soft, or watery flesh.
4. Acquire a blue, green, or brown tint when cut and exposed to the air.
5. The juice is often milky.
6. The odour is commonly powerful and disagreeable.
7. Their taste is bitter, acrid, salt, or astringent.

Dr. Christison places reliance on the astringent styptic taste and disagreeable pungent odour as indicating certainly a poisonous fungus, though some poisonous kinds are devoid of any unpleasant smell.

The symptoms of poisoning from mushrooms are those of marked irritation of stomach and bowels, along with symptoms of brain disturbance. Thus there is colicky pain in stomach and bowels, sickness and purging, faintness and giddiness, dimness of sight, drowsiness, prostration and stupor. Sometimes the symptoms refer mainly to the stomach and bowels, and in other cases the symptoms are more those of a narcotic poison. They may arise very soon after the meal or not for some hours. If vomiting takes place soon, recovery is almost certain. To induce vomiting should be the first effort of treatment, a tea-spoonful of mustard in a tumblerful of hot water being a suitable means, tickling the throat with a feather, passing the finger down the throat, &c.

The poisonous active principle of one form of fungus—the fly fungus or fly amanita (*Amanita muscaria*, see Plate X.)—called muscarin, has been obtained from this fungus, which completely paralyses the heart of a frog, when it is touched with a drop of the solution. There is an antidote to this poison, namely belladonna (deadly nightshade) or its active principle atropina. Of tincture of belladonna 5–15 drops might be given every two or three hours while danger lasted, or, if the liquor atropiæ is to be had, a drop may be given in water every two or three hours. *Note* that belladonna may be given to children without fear. They are less susceptible to its use than adults.

The fungus containing muscarin is said to produce symptoms of intoxication, and symptoms of narcotic poisoning rather than of bowel irritation. Digitalis is also recommended as an antidote. Of its tincture 10 to 20 drops in water may be given repeatedly to an adult, 2 or 3 drops to a child.

The Morel (*Morchella esculenta*) grows in Britain, but is largely imported from Germany in a dry state. It is used for gravies.

Truffles (*Tuber cibarium*) are underground fungi, not growing at all above the surface. They are of a fleshy structure, dark in colour, covered with nodules, varying in size from a plum to a potato. They are found in Wiltshire, Hampshire and Kent in England, especially in oak and chestnut forests. Dogs are trained to un-

earth them, guided by the sense of smell, and in France hogs, which are very fond of truffle, are employed for the same purpose. The truffles chiefly sought after are black and white in colour. The table shows how these two varieties differ in chemical composition. It will be observed that both kinds contain a considerable quantity of nutritive material, much more than mushrooms. They are somewhat indigestible, and are principally used for stuffing and sauces.

LICHEN AND SEA-WEED.

Iceland-moss (*Cetraria islandica*) is a lichen, growing in high latitudes on barren rocks. Its composition is shown in the following table:—

Average percentage Composition of Iceland-moss.

Water	10·0
Nitrogenous	8·7
Starch	70·0
Acids	6·3
Fibre	3·5
Saline	1·5 (Church).

This table indicates that Iceland-moss is of very high nutritive value, and it is frequently made use of, in times of scarcity, by the inhabitants of the rocky coasts where it is found. The acids it contains give it a bitter taste. For use, therefore, it is prepared by steeping in water with a little soda, by which the bitterness is removed. Thereafter it is stewed in water, milk, or soup till it becomes tender and mucilaginous. A spirit may be distilled from Iceland-moss after fermenting the sugar, which may be obtained after transformation of the starchy ingredient. The starch may be transformed into sugar by boiling with weak sulphuric acid.

Reindeer-moss (*Cladonia rangiferina*) is also edible. It is found in mountainous parts of Britain, and in high northern latitudes where it forms almost the sole winter food for reindeer. It also forms a jelly-like substance when cooked.

Rock Tripe (Tripe de roche) is another edible lichen, resorted to for sustenance by Arctic voyagers in distress or by the Arctic hunters of North America.

Irish or **Carrageen Moss** (*Chondrus crispus*) is a sea-weed collected from the rocky shores of the north of Ireland, and found also on the rocky coasts of Britain. Its composition is given in the following table:—

Average percentage Composition of Carrageen Moss.

Water	18·8
Nitrogenous	9·4
Gum, &c.	55·4
Fibre	2.2
Saline	14·2 (Church).

The carbohydrate is in the form of a gummy material, which causes the moss, when steeped in boiling water, to form a stiff jelly. Before being cooked it should be steeped for some hours in cold water. The moss contains some iodine and sulphur, which render it useful in scrofulous conditions.

Laver is a general term applied to sea-weeds. **Green Laver** (*Ulva latissima*) is a common British sea-weed. *Porphyra vulgaris* and *laciniata* (sloke) are other species.

Sea-girdle (*Laminaria saccharina*), also called tangle and sea-wand, is abundant on British coasts. From it mannite, a sugary substance, is obtainable.

Bladder-lock (*Alaria esculenta*) is another sea-weed used as food. *Fucus vesiculosus*, bladder-wrack, has obtained some reputation for reducing corpulency. A liquid extract, called "Anti-Fat," has been advertised for this purpose. Many other sea-weeds, Ceylon moss, Chinese moss, Corsican moss, are also used for food. They are either boiled, after soaking in water, as already described, or pickled and eaten with pepper, vinegar and oil, or with lemon-juice.

II. Non-Nitrogenous Vegetable Foods.

STARCHES OR FARINACEOUS SUBSTANCES.

Starch is derived only from vegetable products. Preceding tables of composition show how abundantly it exists in grains, roots, and tubers, such as wheat, rice, potatoes, &c. In these substances it exists associated with nitrogenous material, but from this material it may readily be separated in a state of purity. For example, in the description of flour it has been shown how the starch may in a very simple way be separated from the gluten. In these food-stuffs the starch exists in the form of granules lying in compartments formed by a nitrogenous material. A starch granule consists of alternating layers of granulose and cellulose, both of which substances are starches; but the latter is extremely insoluble, while the former is dissolved by dilute acids and also by the ferments of the digestive tract. An envelope of cellulose is the outermost layer, and it is ruptured by boiling.

Starch Grains.—Under the microscope a typical starch grain appears as represented in the figure (Fig. 227), the concentric rings being the alternating layers of granulose and cellulose, and the point round which these rings circle is called the hilum. Now starch exists, as has

been said, in a great variety of structures; but the granule of starch varies in size and in appearance according to the plant from which it has been obtained. Thus the starch granule obtained from the potato is very easily distinguishable from that obtained from wheat; both are easily distinguished from the starch grain of Indian corn, and so on. Now the size of the starch grain of all the starches generally used has been very carefully and accurately measured and the appearances well determined, so that it is quite possible to take a mixture of several starches, and after microscopic examination to state definitely the sources of the various kinds in the mixture. If, for example, wheat flour has been adulterated with potato starch, the detection of this is quite easy. In the same way the different kinds of arrow-root can be readily determined under the microscope. The various kinds of starch grain in some of the commoner farinaceous substances are shown on p. 598.

Fig. 227.—Potato Starch Granules.

Starch consists chemically, as explained (p. 536), of carbon, hydrogen, and oxygen only, the hydrogen and oxygen being in proportions to form water. No nitrogen exists. Thus, while starch is eminently valuable for the liberation of heat and energy, by its carbon and oxygen uniting to form carbonic acid gas, and hydrogen and oxygen uniting to form water, it is of no value for the development or repair of tissues. The impossibility of any food-stuffs, such as corn-flour, arrow-root, &c., which consist almost entirely of starch, being made an exclusive food-stuff for any age, is therefore apparent. Starch grains when boiled with water swell up, the cellulose envelopes are ruptured, and the more soluble granulose allowed to come into contact with dissolving juices. After heating in this way starch becomes soluble. Heating to a high temperature converts starch into a form of sugar, and it undergoes a similar conversion when heated with certain acids. This transformation occurs rapidly when starch is brought into contact with ferments, such as the diastase of grain, the ptyalin (p. 143) of saliva, and a ferment in the pancreatic juice (p. 145). It is only when starch has undergone this conversion, either without or within the body, that it becomes useful for purposes of nutrition. Unless the starch granules have been swollen and ruptured by previous boiling with water this conversion cannot readily occur, because of the insoluble nature of the cellulose envelope. The proper cooking of starchy substances is, therefore, of vital importance.

Sago is the starch obtained from various species of palm. The chief are the sago palms (Fig. 228) (*Sagus Rumphii* and *Sagus lævis*), which grow in the islands of the Indian Archipelago, Madagascar, and New Guinea; but from *Cycas revoluta*, a tree common in India, Australia, and tropical America, a coarse sago is also prepared, as well as from other palm-like trees. The trees are cut down just before the appearance of the flower-bud, and the pith, in which chiefly the starch is present, is extracted and reduced to a coarse powder. It is then mixed with water, washed and strained, and the starch allowed to settle. The sediment is then dried, and is the sago flour. Before being sent to the market it may be put through various other processes. It is mixed with water and rubbed into the granular form, which is called granulated sago. Pearl sago is produced by other means, probably with the aid of heat. Sago bread is made by putting the dry meal into heated earthenware moulds, in which it becomes formed into a cake. The *Sagus lævis*, which yields the finest kind, grows in forests in the Moluccas. A single tree will yield as much as from 500 to 800 pounds of sago. Sago is never perfectly free from water, of which, indeed, it contains something like 18 per cent. It also contains 1 to 2 per cent of saline material, the remaining 80 per cent being dry starch. According to Dr. Ed. Smith there are

Fig. 228.—Sago-palm (*Sagus lævis*).

2555 grains of carbon in 1 lb. of sago;

that is to say, $\frac{4}{5}$ths of the pound of sago are pure starch.

Sago is a very bland food, easily digested, and wholesome, but, it must again be repeated, is entirely unsuited for a chief article of food because of its want of nitrogenous constituent.

Corn-flour or Indian-corn flour, is obtained from Indian corn (see p. 565). It is the starch

of the Indian corn, from which by various processes the nitrogenous constituent and bitter element have been removed. It still retains a trace of albuminous material, but not sufficient to be taken into account, in one sample only 18 grains being detected in one pound of the flour. Of pure starch it contains about the same quantity as sago.

Arrow-root is the starch obtained from the tuberous root of a West Indian plant, *Maranta arundinacea* (Fig. 229), now largely grown in Barbadoes, St. Vincent, and Bermuda. It was called the arrow-root plant, it is said, from the belief of the Indians that the root was an antidote to the arrow-poison, if the fresh roots were applied to the wound.

Fig. 229.—Arrow-root Plant.

The tubers when twelve months old are dug up, "well washed in water, and then beaten in large, deep, wooden mortars to a pulp. This is thrown into a large tub of clean water. The whole is then well stirred and the fibrous part wrung out by the hands and thrown away. The milky liquor, being passed through a hair sieve or coarse cloth, is suffered to settle, and the clear water is drained off. At the bottom of the vessel is a white mass, which is again mixed with clean water and drained; lastly, the mass is dried on sheets in the sun." The root furnishes about 26 per cent of starch. The Bermuda arrow-root is most esteemed. Other starches, sold as arrow-root, however, are made from quite different plants, and their source can always be determined by the use of the microscope.

English or **British Arrow-root** is potato starch.

Portland Arrow-root is starch made from the bulb of *Arum maculatum* (Fig. 230), the common "wake-robin," "cuckoo-pint," or "lords-and-ladies." It is manufactured in the island of Portland. An acrid material contained in the bulb is removed by washing.

Fig. 230.—Wake-robin (*Arum maculatum*).

Brazilian Arrow-root is the flour of *Manihot utilissima* (Fig. 232), from which tapioca is prepared—the cassava or tapioca plant, belonging to the natural order *Euphorbiaceæ.*

East Indian Arrow-root is obtained from the tubers of *Curcuma angustifolia,* one of the ginger family of plants, and a species of turmeric.

Tacca Arrow-root or **Tahitan Arrow-root** is derived from *Tacca oceanica,* a native of the South Sea Islands, of the order *Taccaceæ.* Another of the species, *T. pinnatifida* (Fig. 231), found in Asia, yields a starch much used by the natives.

Fig. 231.—Tacca pinnatifida.

Tous-les-mois or **Canna Arrow-root** is yielded by the tubers of *Canna edulis,* a native of the West Indies, of the same order as the plant which yields the true arrow-root, *Marantaceæ.* It is imported from St. Kitts.

Maize Arrow-root is the same as corn-flour.

Rice Arrow-root is the starch of rice, called also rice flour.

The same remarks apply to it as to other starches. It consists of about 82 per cent pure starch.

Tapioca or **Cassava** is the starch from the *Manihot utilissima,* already noted as the source of Brazilian arrow-root. It is a native of tropical America, and is also cultivated in India, Africa, and other tropical countries. The plants contain a bitter poisonous substance, which is removed by washing. The root is washed and scraped, and then reduced to a pulp by being rasped or grated. It is then squeezed to remove the juice. The pulp is then dried and forms cassava powder or manioc. Made into cakes it is called **cassava bread.** The cassava meal dried on hot plates forms irregular little lumps, and this is the tapioca.

Fig. 232.—Cassava Plant (*Manihot utilissima*).

Salep or Salop is the dried tubers of eleven species of orchid, *O. mascula* (Fig. 233), *maculata,*

latifolia, morio, and others. It is imported from Persia and Asia Minor, and is largely used in Turkey and Eastern Europe as food. It occurs in small oval bulbs, whitish-yellow in colour, hard, and semi-transparent, tasting like gum tragacanth, and with a faint peculiar smell. It is ground into powder and boiled with water, milk, and sugar, like other white-puddings. Its exact composition is not stated.

Fig. 233.—Salep (*Orchis mascula*).

SUGARS.

Sugar is a compound of carbon, hydrogen, and oxygen. There are two chief forms of it—the grape-sugars or glycoses, and the cane-sugars, sucroses or saccharoses. To the former class belong the fruit-sugar, to which specially the name glucose, glycose, dextrose, or grape-sugar is given, the sugar found in flesh called inosite, and it is the kind of sugar passed out of the body in the disease diabetes (p. 303). Laevulose, mannitose, galactose are other varieties of grape-sugar. Grape-sugars crystallize with difficulty forming warty little masses, or not at all, and in this they are markedly distinguished from the cane-sugars, which form beautiful crystals. The granular appearance of honey is due to the concretions of the grape-sugar of which it mainly consists.

Of cane-sugars the chief examples are derived from the sugar-cane, beet-root, and other roots, and the birch and maple. Milk-sugar, or lactose, the form in which sugar exists in milk, and maltose, a kind of sugar formed during the fermentation process in the transition to glucose, also belong to the cane-sugar group. Cane-sugar crystallizes readily in prismatic forms. It is more sweetening than grape-sugar.

Another distinguishing feature is that grape-sugar ferments readily; when submitted to the action of yeast it is transformed at once into carbonic acid gas and alcohol. On the other hand cane-sugar requires first to be converted into grape-sugar before it undergoes fermentation. Starch requires to be similarly transformed. In the human body both starch and cane-sugars require similar conversion, under the ferment action of the saliva or pancreatic juice, before they are available for purposes of nutrition. The starch is first transformed into dextrin, a gummy substance, having the same chemical composition as starch, and classed among the starches, but differing from it in being completely soluble in water, and then the transformation to glucose is effected. This same transformation of starch to dextrin, and dextrin to glucose, is effected by the action of the diastase of the wheat grain on the starch of the grain, produced during germination.

Cane-sugar.—The ordinary sugar of commerce is obtained from the sugar-cane (*Saccharum officinarum*), belonging to the natural order of the grasses, *Graminaceæ.* It is a native of India, whence it was transported to Cyprus about the middle of the twelfth century. From Cyprus it reached Madeira, and was transported to America about the beginning of the sixteenth century. It grows 18 to 20 feet in height, has jointed stems, has large firm thin leaves and numerous flowers (Fig. 234). When grown for

Fig. 234.—Sugar-cane.

1, Stem from entire plant in flourish. 2, Cane with leafy offset. 3, Piece of mature cane. 4, A spikelet of the flourish.

sugar, however, they are rarely allowed to come to flower, young plants being produced by offsets from the stem of older ones. It is in the stem of the cane that the sugar abounds, the composition of the stem showing—

Sugar	18	per cent.
Water	72·1	,,
Woody fibre and salts	9·9	,,

From many other plants may cane-sugar be obtained. The stem of the Chinese sugar-cane (*Sorghum saccharatum*) contains it to the extent of 9 to 9½ per cent. "A closely-allied species, called imphee, is grown by the Zulu Kaffirs, and yields not only sugar in its stems but much valuable starchy food in its seeds." The juice

from the stems of maize, cut shortly after flowering, contains cane-sugar to the extent of 3 to 4 per cent. The stems of the American rock-maple (*Acer saccharinum*) yield cane-sugar in richest quantity in early spring. Two holes are drilled in the tree about 20 inches from the ground, and wooden spouts driven into them, by which the ascending sap flows out into troughs placed to receive it. In this sap cane-sugar is present to the extent of 2 per cent. From the stem of the sago-palm (see p. 585) cane-sugar has also been extracted. **Jaggery** is the name applied to a sugar obtained from the juice of various palms, the cocoa-nut palm, the date-palm, the wild date-palm (*Phœnix sylvestris*), and *Caryota urens*, an inferior sago-palm. In roots and tubers of various other plants is it found. Chief of these is the beet-root, the sugar beet, or mangold-wurzel (*Beta vulgaris*). It yields 7 to 11 and even 14 per cent of cane-sugar. The manufacture of beet-sugar is largely carried on in France, Belgium, and Russia, a total of 700,000 tons of beet-sugar being, it is said, prepared in Europe annually, about half the total European import of cane-sugar. Cane-sugar may also be obtained from hazel-nuts, walnuts, coffee-beans, and locust-beans, carob-beans or St. John's bread, which contains it to the extent of 51 per cent (that is, the dry bean).

The following terse account of the method of preparing sugar from the cane is taken from Watt's *Dictionary of Chemistry.* The ripe canes cut close to the ground and stripped of the leaves are crushed between rollers, and the expressed juice, which is apt to run quickly into fermentation by the action of the albuminous matters which it contains, is purified by heating it in a copper boiler to about 140° Fahr., with a small quantity of lime. The impurities then form a scum, which is removed as fast as it collects. The juice, when sufficiently clarified, is rapidly concentrated to about 23° of the hydrometer, then passed through cloth filters and evaporated to a very thick syrup, which is run into shallow vessels to accelerate cooling, then poured into vessels having their bottoms pierced with holes which are kept plugged. The syrup, after being left at rest for some hours, is agitated to promote the crystallization of the sugar, and as soon as it has set into a solid mass, the plugs are removed to allow the still remaining liquid to run off, and the syrup is again boiled till it no longer yields any crystals. The last mother-liquors, which are thick, brown, and refuse to crystallize, are called molasses or treacle, and are used chiefly for the preparation of rum. The solid sugar, obtained as above, is sent to Europe under the name of raw sugar, or Muscovado sugar. It is a yellowish granular powder, still impregnated with treacle, and often contaminated with foreign substances, which impart to it a more or less disagreeable taste; hence it requires refining.

The formation of molasses is entirely due to the conversion of cane-sugar into uncrystallizable sugar by the heat to which the juice is subjected; the fresh juice of sound canes contains nothing but crystallizable sugar. Great improvements have recently been effected in the methods of boiling down syrups, especially by the use of vacuum-pans, whereby a beautiful crystallized product is obtained from the juice at the first evaporation, and the formation of molasses is greatly diminished. To obtain pure, colourless, crystallized sugar from raw sugar, the latter, dissolved in about a third of its weight of water, is mixed with a small quantity of milk of lime, and heated to the boiling point; and the juice is decanted from the impurities, which separate in the form of a crust, then filtered through bone-charcoal, and evaporated in a vacuum-pan. The strongly concentrated juice is made to crystallize by moderating the heat and running in small quantities of unthickened juice, whereupon a magma of sugar-crystals immediately forms. To give them the requisite hardness, heat is again applied, the crystalline magma is left to drain in the sugar-loaf moulds, and the formation of small uniform crystals is promoted by stirring and breaking up the crust which forms on the surface. When the crystallization is complete, the apex of the mould, which has previously been closed, is opened, to allow the syrup to drain off, and that which remains adhering to the crystals is displaced by pouring in pure sugar syrup. By due desiccation (drying) the loaf-sugar or refined sugar of commerce is obtained.

Formerly the clarification of the syrup was effected by adding a certain quantity of the serum of bullocks' blood; on heating the syrup, the albumen of the serum became coagulated and rose to the surface, carrying with it the greater part of the impurities.

When it is not desired to make loaf-sugar the uncrystallizable syrup is removed by centrifugal machines, revolving drums covered with fine wire-gauze, caused to turn with great speed, by which the syrup is thrown out through the gauze, while the sugar is retained in the drum.

In the refining process treacle and golden syrup are obtained. Treacle is the uncrystal-

lizable portion separated from the crystals in the draining process. It contains water, some crystallizable sugar in solution, saline matters and impurities, and about 65 per cent of uncrystallizable or fruit sugar, due to conversion of cane into fruit sugar by the heat. Syrup is clarified treacle, obtained by re-boiling the treacle and filtering through animal charcoal. Coloured moist sugars are less refined qualities, containing more water, uncrystallizable sugar, and various impurities. Sugar in the largest crystals is of the purest kind; sugar-candy is the purest kind of sugar. There is always a proportion of water in sugar, roughly indicated by the degree of moisture. The purest white sugar contains 99·92 per cent of sugar, the remainder being ·069 per cent of absorbed moisture, 1·02 per cent of ash. In inferior qualities the quantity of sugar may be reduced to 94, 88, 80, and 67 per cent. The sweetening qualities of sugar will, therefore, vary; and the diminished sweetening quality of the inferior kinds is marked, because of the considerable proportion of fruit-sugar they contain, whose sweetening property is much less than that of cane-sugar.

There are 2800 grains of carbon in 1 pound of moist sugar.

Caramel is produced from cane-sugar by heating to 1600° Fahr., by which water is driven off, the sugar ceases to be able to crystallize, is dark coloured, and becomes bitter in taste. It is used by cooks for flavouring and colouring.

Honey is a vegetable product. It is the sweet juice produced in the nectaries of plants at the base of the petals. It appears simply to be collected and stored by the bees, and not to undergo any chemical change while it remains in the honey-bag of the bee, which is a dilatation of the gullet or œsophagus. The quality of the honey is therefore mainly affected by the nature of the plants from which it is obtained. "In Scotland the best honey is gathered in the months of June and July, when the white clover (*Trifolium repens*) is in bloom; and what is stored in spring, or rather in April and May, is finer and better flavoured than what is obtained in autumn, unless the bees have been during the latter season within reach of heath, the honey from which is of a rich wild flavour, but of a darker colour. The quality of honey is, of course, much influenced by the nature of the plants most frequented by the bees. The famed honey of Hymettus derives its excellence, it is said, from the wild thyme growing so luxuriantly on the celebrated mountain from which it derives its name; that of Narbonne, from the wild rosemary (*Rosmarinus officinalis*). The white Dutch clover and the heath have been already noticed as furnishing honey of a superior kind; and there is a district in Galloway, North Britain, where perhaps the best honey in the kingdom is produced, owing, it is supposed, to the great abundance of wild thyme (*Thymus serpyllum*) with which the country abounds." Honey of a deleterious nature is sometimes met with. "Towards the close of the year when flowers become scarce, and in those parts of the country where alders abound, and where onions and leeks are cultivated on a large scale, and allowed to run to seed, the bees, from taste, or from necessity, or from anxiety to complete their winter stores, are seen to feed on these plants, which communicates to the honey a very disagreeable flavour. But this is not all. The fact stated by Xenophon in the *Retreat of the Ten Thousand*, and confirmed by Diodorus Siculus, proves that there are plants in Asia Minor which give to the honey, not only disagreeable, but poisonous qualities. He tells us that the soldiers, having eaten a quantity of honey in the environs of Trebizonde, were seized with vertigo, vomitings, &c. This effect was attributed to the rose-laurel (*Rhododendron ponticum*), and yellow azalea (*Azalea pontica*). Father Lamberti also assures us that a shrub of Mingrelia produces a kind of honey which causes very deleterious effects. It is quite possible that the poisonous juices extracted from these plants might be innocuous to the bees themselves. . . . Sir J. E. Smith asserts that the nectar of plants is not poisonous to bees, and an instance is given, in the *American Philosophical Transactions*, of a party of young men who, induced by the prospect of gain, having removed their hives from Pennsylvania to the Jerseys, where there are vast savannahs, finely painted with the flowers of the *Calmia angustifolia*, could not use or dispose of their honey on account of its intoxicating quality; yet 'the bees increased prodigiously;' an increase only to be explained, says Dr. Bevan in his *Honey-Bee*, by their being well and *harmlessly* fed."

Bees are found in all temperate and warm climates. The bee cultivated in Europe is the *Apis mellifica;* the red honey of Surinam and Cayenne is produced by the *Apis amalthea;* and in Madagascar honey of a greenish colour is obtained from the *Apis unicolor*, a black bee.

Honey consists of cane-sugar, fruit-sugar or glucose, and inverted sugar (a mixture of two varieties of glucose, namely dextrose and lævu-

lose). Along with these there is also a trace of flavouring and colouring substances and wax. There are also pollen from the plant "and invariably minute quantities of alcohol." The total quantity of sugar, mainly grape or fruit sugar, is not less than 73 per cent, and there is not more than 27 per cent of water.

Virgin Honey is the term applied both to honey from young bees that have never swarmed, and to honey obtained from the comb without the aid of heat or pressure, simply by allowing it to drain from the comb.

Honey which has been kept for some time, or has been obtained from the comb by the aid of pressure and heat, crystallizes owing to the formation of the small warty masses of dextrose. It is less delicate in flavour than clear virgin honey.

Mead, or metheglin, is an alcoholic liquor obtained by the fermentation of honey, varying in sweetness according to the extent to which the fermentation has been carried. It was a drink much consumed in England in olden times.

Manna is a sugary exudation from certain plants and trees, especially of the ash tribe. The manna of commerce is obtained chiefly from two kinds of ash, *Fraxinus ornus* and *Fraxinus rotundifolia*, by making incisions in the stems of the trees. The juice escapes and dries into crystalline masses, which are collected. The trees are cultivated for the purpose chiefly in Sicily and Calabria. A similar substance can be obtained from the common ash (*Fraxinus excelsior*). Other sugary exudations, known under the name of manna, are obtained from other sources, Briançon manna from the leaves of the common larch (*Larix europœa*), another from Mount Lebanon, from the branches of *Pinus cedrus*. Manna is also yielded by the *Eucalyptus mannifera*, the dwarf oak, tamarisk, and other plants. That of the last named is called **Manna tamariscina**, or **Manna Israëlitarum**, and is believed by Landerer to be the manna mentioned in the Old Testament. "He informs us that this exudation is produced by the puncture of *Coccus manniferus*, an insect inhabiting the trees of *Tamarix mannifera*, which grow abundantly in the neighbourhood of Mount Sinai. The manna exudes as a thick transparent syrup, covering the smaller branches from which it flows. It is collected by the monks of the district in the month of August. The collection takes place very early in the morning, at which time, owing to the coolness of the night, the saccharine juice has become to some extent congealed. The tamarisk manna is eaten in Palestine and in the district of Sinai as a delicacy." The manna may be shaken from the trees on which it has collected before sunrise, into cloths spread underneath. It is also found upon sand and stones; and in the state in which it is found it resembles coriander seed. **Honey-dew** is a similar sugary exudation found on many plants, principally oak, elm, plane, lime, beech, and fruit trees and evergreen plants. It is found at the close of summer on very sultry evenings.

Manna consists largely of a peculiar kind of sugar, called mannite; according to one authority 60 per cent is mannite, and a large percentage of uncrystallizable sugar; according to another analysis the tamarisk manna consists of cane-sugar 55 per cent, inverted sugar 25 per cent, and dextrin (a gum) 22·5 per cent.

It has an aromatic flavour, and is now chiefly used as a mild laxative for children, from 60 grains up to ½ ounce being the dose.

VEGETABLE OILS.

Oil is yielded by a very large number of vegetable products, from nuts like the palm-nut, the walnut, almond, hazel-nut, ground-nut, from other fruits like the olive, and especially from seeds, such as those of the cotton plant, mustard seed, cucumber seed, rape seed, &c.

To understand the richness of some of these in oil reference need only be made to the tables on pages 580 and 582, where it is found that the quantities of oil yielded by 100 pounds of the substances are very great. Thus—

100 pounds of			
Filberts	yield over	66	pounds of oil.
Walnuts	,,	62	,,
Almonds	,,	53	,,
Ground-nuts	,,	50	,,
Cocoa-nuts	,,	35	,,

To these we may add the following—

100 pounds of			
Palm-nut (pulp)	yield	72	pounds of oil.
Sesame seeds	,,	51	,,
Olives (kernels)	,,	44	,,
Linseed	,,	38	,,
Cotton seed	,,	24	,,
Sunflower seeds	,,	22	,,

Olive-oil is expressed from the pulp of the ripe olive, the fleshy exterior of the fruit. The common olive-tree (*Olea europœa*, Fig. 235) is a native of Syria, and is cultivated in Italy, France, Spain, Turkey, &c. It is a pure bland oil, well suited for domestic purposes. The first

oil pressed from the ripe fruit is greenish in colour, and is the finest—virgin oil it is called. Provence oil (produced in Aix), Florence oil, Lucca oil, Genoa oil, and Gallipoli oil, are all olive-oils of good quality, the first being most esteemed. Sicily oil is also olive-oil of an inferior quality, and Spanish oil is the worst kind, being used for machinery. The olive fruit itself is not only used for obtaining oil but is preserved as a pickle, and used after dinner to refresh the palate for the taste of wine. The fruit is pickled while still green—the ripe fruit is black—it is soaked in strong soda solution to remove a bitter principle, then in fresh water, and afterwards transferred to a solution of salt in which it is preserved.

Fig. 235.—Olive (*Olea europæa*).

Palm-oil is mainly used in Britain as a lubricant. It is, however, used on the Gold Coast as a butter, and when pure and fresh is wholesome. It is obtained from several species of palm, chiefly the oil-palm, *Elæis guineensis* (Fig. 236), the oil being expressed from the fruit, palm-nuts.

Fig. 236.—Palm-oil Tree (*Elæis guineensis*).

Fig. 237.—*Sesamum orientale* (Sesame).

Sesame-oil is a fine bland oil, used in India as an article of food, and elsewhere for burning in lamps, as well as for adulterating olive-oil. It is expressed from the seeds of *Sesamum orientale* (Fig. 237), natural order *Pedaliaceæ*, native to India and also cultivated in Egypt and Syria.

Cotton-seed Oil, unlike linseed-oil, is an extremely pleasant oil, and fitted to be used as a food-stuff. It is cheaper than lard, and might with great advantage be used instead of it for cooking in oil. "The very best lard," Williams says, "or ordinary kitchen butter, eaten cold has more of objectionable flavour than refined cotton-seed oil." Moreover, the present price of the best refined cotton-seed oil is 3½*d.* per lb., while lard costs 6*d.* per lb. wholesale. It is expressed from the seeds of *Gossypium barbadense,* of the natural order *Malvaceæ.*

Cucumber-seed Oil. Common cucumber (see p. 574) seeds also yield an oil, said to be of delicious and delicate flavour, and the large cucumber grown on the African coast yields from its seeds an oil which "far exceeds in flavour the finest olive-oil."

Shea or **Galam Butter** is a vegetable fat obtained from the nuts of *Bassia Parkii,* of the natural order *Sapotaceæ,* natives of India, Africa, and America. The sapodilla plum is the produce of a species of the same order, which is rich in trees and shrubs useful for alimentary purposes. A species of the same order is the tree which produces the gutta percha of commerce, *Isonandra gutta.* The nuts of *Bassia Parkii* are shelled, and the kernels, which consist almost wholly of fat, are boiled with water and pressed. The fat is greenish white, and solid at ordinary temperatures, and has a mild pleasant flavour. Many other kinds of Bassia yield oils which, in the Gaboon and elsewhere where they are produced, are used by the natives as an external application for rheumatism.

III. Condiments.

Condiments are substances which are not foods in themselves, but are taken with foods for the purpose of aiding their flavour.

The chief condiment is salt. It, however, stands on quite a different level from the others. It is a necessity, and its importance has been already dwelt on (p. 539). The other condiments we might classify in the following way:—

Acids: Vinegar, lemon-juice, pickles, &c.

Pungent substances: Pepper, mustard, ginger, curry, horse-radish.

Aromatics: Cinnamon, nutmegs, cloves, allspice, mint, mace, parsley, cardamoms, thyme, caraway, coriander, angelica, marjoram, fennel, dill, anise, sage, vanilla, turmeric, chervil, cumin, capers, onion, garlic, shallot, chives, savory, tarragon.

None of these is necessary for foods. They are added for the purpose of giving a fillip to the appetite, and where there is any feebleness of appetite they cause more food to be eaten

than would otherwise be. They also relieve the monotony and sameness of food, and where natural appetite is wanting they act beneficially in this way. They also act upon the mucous membrane of the stomach, and stimulate the flow of blood to the glands and of gastric juice; and thus undoubtedly they will stimulate digestion, where such stimulation is needed. Vinegar, by the addition of acid which it makes, will also further aid digestion where the acidity of the gastric juice is too feeble. In a state of health, however, there is no need for such stimulation, and if they are resorted to, to any great extent, specially the more active condiments, the stomach and bowels are likely to become so used to their sharp stimulating action that they will not respond to any less active stimulant. The mere entrance of the food into the stomach is, in health, the only incitement required to promote the flow of the gastric juice, but will be totally insufficient for the stomach accustomed to the rousing action of spices, curries, and aromatics of various kinds. They ought, therefore, always to be employed with great moderation, and the milder of them rather than the more active and pronounced. They should not be permitted to children at all.

Vinegar owes its acid properties to acetic acid, of which it ought to contain 5 per cent, that is, 5 per cent of the pure crystallizable acetic acid, which is also called glacial acetic acid. There are two chief processes by which vinegar is made. The first is by conversion of alcohol into acid, which is effected by the acetic acid fermentation, now known to be due to the activity of an organism, the *Mycoderma vini*, just as alcohol is the result of a fermentation due to the activity of another organism, the *Torula cerevisiæ* (p. 389). So that vinegar is made from sugar, or starch which has been converted into sugar, after it has undergone two fermentations, first into alcohol and second into acid; and the souring of wines is the result of the production of acid by the agency of organisms which have gained access to the wine. The material from which vinegar is produced by this fermentive process is either wine or malt, and thus there are **Wine-vinegar**, produced on a large scale in France, and **Malt-vinegar**, produced in England. The second process is by the destructive distillation of wood. This produces **Wood-vinegar, or Pyroligneous Acid.** The flavour of the particular vinegar depends upon its source. For, besides the 5 per cent of pure acetic acid which it ought to contain, and water, which makes up almost the remainder of its bulk, there are present in minute quantity various substances dependent upon the source of the vinegar, which give it the special flavour it may possess, as well as salts, extractive matter, alcohol, sugar, gum, and probably some colouring matter purposely added by the manufacturer. Flavouring essences are also frequently added.

Wine-vinegar is prepared from grape juice and inferior new wines, that made from white wine is specially desired. The wine is kept in large casks at a fixed temperature, and the fermentation occupies generally a fortnight. Thereafter the vinegar is run off into barrels, in which are several chips of birch wood, and there clarified. Or the wine is placed in large casks containing beech shavings, which afford space for the growing organism, and when the wine has become converted into vinegar, half is run off and the cask then filled up with more wine, so that the "mother" casks, as they are called, are never emptied, and the process of manufacture goes steadily on.

Malt-vinegar is obtained from a mixture of malt and raw barley, mashed with water, and allowed first to undergo the vinous fermentation, and subsequently the acetic acid fermentation. A long time—weeks or months—is occupied in the process.

Vinegar may, of course, be made from sugar by submitting it to the double fermentation. It might, therefore, be called **sugar-vinegar.**

Wood-vinegar is made by heating wood in large iron cylinders, which are connected with condensers. The liquid which passes over from the cylinders consists of wood spirit, acetic acid, water, and tarry products. By redistillation the pyroligneous acid is separated out in a crude state, containing tarry matter. By various chemical processes the acetic acid is separated from the tar by conversion into acetate of sodium, the acetic acid then liberated by decomposition with strong sulphuric acid, and finally purified by distillation.

Vinegar usually contains some sulphuric acid, added to prevent decomposition, though that has been shown to be unnecessary, and allowed by law to the extent of one-thousandth part by weight. It is usually sold in four degrees of strength, called Nos. 18, 20, 22, and 24, of which the last is the strongest, and is the best for pickling. No. 22 is the best for the table.

Vinegar is used by itself, also in the preparation of sauces, and for the making of pickles, for which all kinds of vegetables may be used. Copper has been added to vinegar in order to give the vegetables a bright green colour. It

is, of course, injurious, and its presence may be detected by inserting the bright blade of a steel knife, which will become coated with the coppery colour. It is useful for allaying thirst and checking excessive perspiration. It is a popular remedy for corpulence, and does, when habitually taken, cause diminution of stoutness to occur, but by interfering with the digestive process and producing a failure of nutrition. Used regularly for such a purpose it is undoubtedly hurtful.

Lemon and **Lime Juice** owe their special properties to the presence of citric acid, which is found also in the citron, orange, shaddock, and other fruits. It is prepared in England, and also in Sicily and the West Indies, some brandy being added to the juice to preserve it, and sometimes it is preserved by simple boiling. The juice should contain 32½ grains of citric acid in each fluid ounce, and with it there is malic acid, gum, extractives, and water. It is an agreeable and refreshing beverage, and is regularly employed in the merchant navy as a preventive of scurvy, 1 ounce of juice, 1 ounce of sugar, and half a pint of water being daily served out to each of the crew. An artificial lemon beverage may be prepared by dissolving 552 grains of citric acid in a pint of water and flavouring with essence of lemon; or the following: 1¼ oz. citric acid, 45 grains carbonate of potash, 2½ oz. white sugar, dissolved in 1 pint of cold water, flavoured with essence of lemon or the rind of a lemon, and after 24 hours strained through a hair-sieve or piece of muslin.

Pepper is the fruit of a set of herbs belonging to the natural order *Piperaceæ*, or pepperworts, which flourish in the tropics. **Black-pepper** is the fruit of *Piper nigrum* (Fig. 238), dried while still unripe. The plant is a climbing one, supporting itself on other trees, and growing to a height of 8 to 12 feet. Its berries pass from the green to the red stage and then become black, but previous to this they are gathered and dried in the sun; they occur in small clusters, 20 to 50 in each. **White-pepper** is the same fruit deprived of its outer husk. The best black-pepper comes from Malabar; but what is sold in the shops consists of a mixture of berries from different localities—Malabar, Penang, Sumatra, &c. **Long-pepper** is the fruit of *P. longum* (Fig. 239), native to Java, Malabar, and Bengal. **Jamaica-pepper**, or **Allspice**, or **Pimento** (Fig. 240), is the berry of *Eugenia pimenta*, belonging to the *Myrtaceæ* order, to which cloves, cajeput, guava, and eucalyptus belong. It is imported from Jamaica. Its peculiar aroma, supposed to resemble a mixture of cinnamon, cloves, and nutmeg, have earned for it the name of allspice. **Cayenne-pepper** is made from the powdered pods of *Capsicum annuum*, of the same order as potato, *Solanaceæ*. It is sold entire under the name of **Chillies**. It is native to America, and is imported chiefly from Zanzibar and Natal. Guinea-pepper, cherry-pepper, bell-pepper, goat-pepper are all obtained from different kinds of Capsicum.

Fig. 238.—Black-pepper (*Piper nigrum*).

Fig. 239.—Long-pepper (*Piper longum*).

Fig. 240.—Pimento.

All these substances owe their peculiarities to the presence of an essential oil, which in black and white pepper exists to nearly 2 per cent.

Mustard is the finely ground seeds of *Sinapis nigra* or *alba*, black or white mustard, or a mixture of both. They belong to the cruciferous order. From the white mustard 36 per cent of a clear yellow odourless oil, void of all pungency, can be expressed, and from the black mustard 18 per cent. If the flour, left from the black mustard, be moistened with water a volatile oil is formed, which did not previously exist, to which the pungent qualities are due, and which is developed, owing to the moistening, from a substance called myronic acid. White mustard contains no such acid, and does not develop pungency by moistening. This volatile oil is produced only to the extent of ·2 per cent.

Fig. 241.—Mustard (*Sinapis nigra*).

Horse-radish (p. 572) belongs to the same order as mustard, and yields a volatile oil similar to that of black mustard.

Ginger is the scraped and dried root of *Zingiber officinale* (Fig. 242), of the order *Zingiberaceæ*, tropical plants, widely cultivated in East and West Indies, China and Africa.

Fig. 242.—Ginger Plant (*Zingiber officinale*).

Curry of Ceylon is said to be a mixture of the following: a piece of green ginger, two fragments of garlic, a few coriander and cumin seeds, six small onions, one dry chilli, eight peppercorns, a small piece of turmeric, half a dessert-spoonful of butter, half a cocoa-nut, and half a lime; to have it in perfection it should be made on the day on which it is to be cooked. Ordinary curry powder is a mixture of turmeric, black-pepper, coriander seeds, cayenne, fenugreek, cardamoms, cumin, ginger, allspice, and cloves.

Belonging to the ginger order are some of the aromatic condiments.

Turmeric is an example, the root-stock of *Curcuma longa*, an East Indian plant, imported chiefly from Bengal and Peru. It is used both as a dye, of a yellow colour, and also as a condiment in powder. Its odour is due to an essential oil, which it contains to the extent of 1 per cent.

Cardamoms are also aromatic fruits of the ginger order. The medicinal cardamoms are derived from *Elettaria* (*Alpinia*) *Cardamomum*, Malabar cardamoms. A large kind (*Amomum angustifolium*) comes from Madagascar, a smaller (*Amomum cardamomum*) from Sumatra. **Grains of Paradise** or Ceylon cardamoms belong to the same order, and are the fruit of *Amomum melegueta*, a West African plant.

Of the aromatic group the following belong to the natural order *Umbelliferæ*:—

Parsley (*Apium Petroselinum*) is a native of Sardinia, yielding both a fixed and volatile oil.

Fennel (*Fœniculum vulgare*) grows wild on the Mediterranean shores, of which both seeds and leaves yield an essential oil: chopped leaves are sometimes served in melted butter to mackerel: cordials are flavoured with the fruit.

Cumin (*Cuminum cyminum*) is native to Egypt and Syria; the essential oil of cumin is used for flavouring cordials, and is obtained from the seeds: cumin resembles fennel.

Dill (*Anethum graveolens*), native to Southern Europe, very much resembles fennel. Its essential oil dissolved in spirit yields, when diluted with water, dill water, a useful and harmless agent for dispelling wind from the bowels of children.

Anise (*Pimpinella anisum*) is native to Asia Minor and Egypt, and cultivated in Spain and Malta. The fruit contains 2 per cent of essential oil, used for flavouring cordials: sugar flavoured with the oil is used for flatulence.

Caraway (*Carum Carui*) has a root like carrot or parsnip, and may be used as they are: seeds are imported from Holland: an essential oil is yielded by the seeds, and is used for flavouring cakes, confectionery, cordials, &c.

Fig. 243.—Coriander (*Coriandrum sativum*).

Coriander (*Coriandrum sativum*), native to Southern Europe, is cultivated in France: the seeds are used and yield also an essential oil.

Angelica (*Archangelica officinalis*), found in Northern Europe, possesses a large fleshy aromatic root, which is boiled in syrup and used as a sweetmeat; the seeds are used as flavouring agents for cordials, &c.

Chervil (*Anthriscus cerefolium*) or garden chervil, native to Britain, a hairy herb, is used for flavouring soups and salads; sweet chervil is *Myrrhis odorata.*

The natural order *Labiatæ* yields a large number of sweet, savoury, or pot herbs:—

Mint or **Spearmint** (*Mentha viridis*) and peppermint (*M. piperita*) and pennyroyal-mint (*M. pulegium*) all yield essential oils.

Thyme (*Thyma vulgaris*), a Mediterranean shrub; wild thyme (*T. Serpyllum*) is a British plant: the essential oil is called origanum oil.

Marjoram (*Origanum vulgare*) is a native of Britain: sweet marjoram is *O. marjorana,* and is much used for culinary purposes because of its fragrance.

Sage (*Salvia officinalis*), native of Southern Europe, is a garden plant; wild sage (*S. Verbenaca*) is a native of Britain, and also meadow-sage (*S. pratensis*).

Sweet Basil (*Ocymum basilicum*), native of India, is specially used in France for flavouring soups, sauces, &c., like the other pot-herbs.

Savory (*Satureia hortensis*) is a garden shrub cultivated in Europe for seasoning sauces.

To the order *Liliaceæ* belong the following:—

Garlic (*Allium sativum*), a bulbous perennial, native to Southern Europe, much resembles onion, but is of stronger flavour and odour: the

bulb consists of ten or twelve "cloves" inclosed in a tough coat.

Shallot or **Eschalote** (*Allium ascalonicum*) is a native of Palestine, especially near Ascalon: it is one of the mildest of the onion tribe.

Chives or **Cives** (*Allium schœnoprasum*) is native to Britain, and is used as are leeks or onions.

Capers are the flower-buds of *Capparis spinosa*, of the natural order *Capparidaceæ*, growing in the south of Europe: it is a low wall

Fig. 244.—Caper (*Capparis spinosa*).

Fig. 245.—Cinnamon (*Cinnamomum zeylanicum*).

plant, of which the flower-buds are collected before expanding and placed in vinegar.

Cinnamon and **Cassia** are derived from the bark of a tree of the genus *Cinnamomum*, of the order *Lauraceæ*. The former is yielded by *C. zeylanicum*, an evergreen tree of Ceylon, Borneo, Sumatra, and the coast of Malabar. It is in the form of quills, the inner bark stripped from two-year-old shoots. Cassia is a Chinese species, the unripe fruit of which is "cassia buds." White cinnamon comes from a different order, being the bark of a West Indian tree, *Canella alba*, of the order *Canellaceæ*. It is also an aromatic.

Nutmegs are the kernel of the fruit of *Myris-*

Fig. 246.—Nutmeg (*Myristica moschata*).

tica fragrans, of the order *Myristicaceæ*. The nut is within the fleshy fruit, and is surrounded by an arillus or extra covering. This when dried and ground, is known as **Mace**. The tree grows in the East and West Indies, Banda Isles, Sumatra, Brazil, &c. The nutmeg yields 6 per cent of an essential oil of a powerfully aromatic taste. Mace yields 4½ per cent of an aromatic oil.

Cloves are the dried flower-buds of *Eugenia caryophyllata*, of the myrtle order. It is a handsome evergreen tree, native to the Moluccas, and cultivated in Zanzibar and West Indies. The buds are rich in a volatile oil—oil of cloves—yielded by other parts of the plant also.

Fig. 247.—The Clove Plant.

Tarragon (*Artemisia dracunculus*) belongs to the *Compositæ* order, native to Siberia, and cultivated in France. Wormwood belongs to the same species; also mugwort and southernwood. In France it is used for flavouring vinegar and salads.

Vanilla, so much used in the form of an essence for flavouring purposes, is derived from the pods of an orchid, specially *Vanilla planifolia*, native to tropical America. It can now be made artificially from pines.

Fig. 248.—Vanilla.

Animal and Vegetable Foods Compared.

It will now be of interest to contrast animal and vegetable foods from the point of view of their nutritive value so far as that is indicated by their chemical composition. This will be best done by taking typical foods representative of each class. The following table shows the composition of various foods, selected from tables already given, and chosen because of their representative character. The water, saline constituents, fibre, &c., have been omitted, and only the percentages of the useful nutritive ingredients given.

Average Percentage Composition of various Animal and Vegetable Foods.

	Lean Beef.	Fowl.	Eggs.	Cows' Milk.	White-fish.	White Bread.	Scotch Oatmeal.	Haricot Beans (dried).	Potato.	Cabbage.	Figs (dried Turkey).	Sago.
Nitrogenous	19·3	22·65	14·0	4·65	18·5	6·82	16·1	20·81	2·3	1·89	6·1	—
Carbo-hydrates (sugar, starch, &c.)	—	—	0·0	4·28	—	52·34	63·0	53·63	19·7	4·87	65·9	80·0
Fat	3·6	3·11	11·0	3·50	3·0	·77	10·1	2·28	0·3	0·20	0·9	—
Totals	22·9	25·76	25·0	12·43	21·5	59·93	89·2	76·72	22·3	6·96	72·9	80·0

If now, using this table, we reckon up the total nutritive material contained in each of these materials, and, instead of expressing the result in percentages, express it per pound, we get results tabulated in the table that follows.

Total Nutritive Material in 1 lb. of the following Substances:—

Oatmeal	·892 of a lb.,	or fully	$14\frac{1}{4}$	ounces in the lb.
Sago	·800	,, ,,	$12\frac{3}{4}$	,,
Haricot beans....	·767	,, ,,	$12\frac{1}{4}$	,,
Figs	·729	,, ,,	$11\frac{1}{2}$	,,
White bread	·599	,, ,,	$9\frac{1}{2}$	,,
Fowl	·257	,, ,,	$4\frac{1}{10}$	,,
Eggs	·250	,, or exactly	4	,,
Beef	·229	,, or fully	$3\frac{1}{2}$	,,
Potato	·223	,, ,,	$3\frac{1}{2}$	,,
Fish	·215	,, or barely	$3\frac{1}{2}$	,,
Milk	·124	,, ,,	2	,,
Cabbage	·069	,, ,,	$1\frac{1}{10}$	,,

This method of estimating total nutritive ingredients in the pound is not, however, entirely satisfactory, as a glance at the table shows. Oatmeal reigns there pre-eminent, and rightly so. Tested in any way one pleases, it maintains its pre-eminence as the most nourishing food that can be found, as a half more nourishing than white bread, weight for weight, and twice more nourishing than beef. But this method of calculation places sago second in the list, and that pre-eminence is undeserved. It is quite true that one pound of sago contains $12\frac{3}{4}$ ounces of nutritive material, but that is entirely in the form of starch, no albuminoid material being present, so that, while of great value as an energy-producing food, it is useless for tissue repair. If, then, we separate out the total nutritive material, and estimate how much of it is nitrogenous or albuminoid material, and how much is fat and carbo-hydrate, we shall see at once the relative value of the different foods (1) for tissue growth and repair, and (2) for liberation of energy—fats and carbo-hydrates going together for this purpose. The result is shown in the next tables.

Tissue-forming Material in 1 lb. of the following Substances:—

Fowl	$3\frac{6}{10}$ ounces per lb.
Haricot beans.........	$3\frac{3}{10}$,,
Beef......................	3 ,,
Fish......................	$2\frac{6}{10}$ ounces per lb.
Oatmeal................	$2\frac{1}{2}$,,
Eggs	$2\frac{1}{4}$,,
Bread......................	1 (fully) ounce per lb.
Figs......................	1 (scarcely) ,,
Milk	$\frac{3}{4}$ (barely) of an oz. per lb.
Potato..................	$\frac{4}{10}$,, ,,
Cabbage................	$\frac{3}{10}$,, ,,
Sago	Nothing.

Energy-yielding Material in 1 lb. of the following Substances:—

Sago......................	$12\frac{8}{10}$ ounces per lb.
Oatmeal................	$11\frac{7}{10}$,,
Figs......................	$10\frac{7}{10}$,,
Beans	9 (barely) ,,
Bread....................	$8\frac{1}{2}$,,
Potato..................	$3\frac{2}{10}$,,
Eggs	$1\frac{3}{4}$,,
Milk......................	$1\frac{1}{4}$,,
Cabbage	$\frac{8}{10}$ of an ounce per lb.
Beef......................	$\frac{1}{2}$ (fully) ,,
Fowl......................	$\frac{1}{2}$ (barely) ,,
Fish	$\frac{1}{2}$,, ,,

We may observe further that if complete justice were to be done in such a comparison as this, a distinction would require to be drawn between those food-stuffs whose energy-yielding material consisted largely of fat, and those whose energy-yielding material consisted almost exclusively of starch. We have seen (p. 532) that, weight for weight, fat yields fully twice the energy that starch does. Thus the $12\frac{3}{4}$ ounces of energy-yielding material in sago are all starch, while in oatmeal of the $11\frac{7}{10}$ths energy-yielding substance, $1\frac{6}{10}$ths are fat. Counting the $1\frac{6}{10}$ths fat to be equal to $3\frac{2}{10}$ths starch (and it is fully that), then the oatmeal would contain really $13\frac{2}{10}$ths energy-yielding material as starch, and would thus head the list. In the same way eggs would take a much higher place, because its $1\frac{3}{4}$ ounces of energy-yielding substance are all fat, equal to something like 4 ounces of starch, or even more. They would thus rank above potatoes, whose energy-containing material is almost exclusively starch. Beef, fowl, &c., would thus also take higher places, because of the 3 to $3\frac{1}{2}$ per cent of fat they contain.

The result of such a comparison is to show

that the vegetable foods contain the greatest amount of nourishment in a given weight, and to give them a position as energy-yielding foods to which none of the animal foods can approach, but also to indicate that animal foods possess a value for growth and repair of tissue which excels all vegetable foods, and is only approached by beans (and, of course, foods of the same kind, such as peas and lentils) and oatmeal.

We must not, however, stop at this point. These considerations arise from viewing the chemical composition of the various food-stuffs. We must not forget to consider them from the point of view of the human body, which desires to extract from them this nourishment which they contain; in short, we need to consider the digestibility of the various materials. The result is to modify very materially the position that chemical considerations give to some of the vegetable foods, and notably to beans, peas, &c. In particular, the tissue-repairing material they contain is less readily extracted from them than from most animal foods, and the extraction involves greater waste material to be expelled. When such considerations, and they are detailed on p. 604, are taken into account, the inevitable conclusion is that for the yielding of material for growth and repair of tissues animal foods are unapproached except by oatmeal.

THE ADULTERATIONS OF FOOD-STUFFS, AND UNWHOLESOME FOOD.

Adulteration consists in the addition of some substance foreign to the food-stuff, not acknowledged in its sale and not necessary for its manufacture or preservation. Such substance is usually added to increase the profit on the sale of the article by adding to its weight, such as water injected into beef or added to milk, and plaster of Paris added to flour; or an inferior and cheaper article is added closely resembling the fine quality, such as potato starch to flour or St. Vincent arrow-root, or margarine to butter; or the adulteration is for the purpose of enhancing the appearance of the article sold, such as alum to give whiteness to bread, or copper to brighten the appearance of preserved green vegetables, or colouring matter such as annatto to butter.

The detection of adulteration and its nature are the work of expert chemists, but a few simple domestic methods for some of the best-known articles may be usefully mentioned here.

The detection of the addition of water to milk has been mentioned on p. 551, and to butter on p. 556. The presence of solid matter in milk, such as chalk or starch, to give increased opacity to milk, is detected by the microscope.

Bread. "There is little adulteration of bread," says Wynter Blyth, "save with alum. The long and formidable list of substances supposed to be used by fraudulent bakers, such as sulphate of copper, peas, beans, &c., is drawn from rare instances, or from times of famine, or is based upon theory rather than observation. Bakers' bread in this country, taking it as a whole, is of fair purity and is wholesome. Where the customer is cheated is mainly in weight; here there are really serious and continuous frauds. Notwithstanding inspectors of weights and measures, such frauds are practically unchecked, and only limited by the prudential conscience of the baker." Blyth recommends a ready method of detecting alum in bread, which it will be well to give, as it is of very simple application. "The materials required for the test are a solution or tincture of logwood, to which a sufficient quantity of carbonate of ammonia has been added to render it strongly alkaline, and some slips of gelatin. A slice of the bread is then crumbled into a glass and covered with pure water, a slip of gelatin is added, and the whole allowed to stand overnight. In the morning the swollen and softened slip of gelatin is removed and stained with the ammoniacal logwood. If no alum is present, the gelatin will be of a dark pink or red colour; but if the bread contain alum, the gelatin will be coloured various shades of blue, from a barely-perceptible purple up to quite a decided blue, according to the quantity of alum present." The same solution of logwood simply painted over a piece of suspected bread will indicate by a blue colour if alum be present.

Flour, Arrow-root, Ground Rice, &c., are examined for adulteration by means of the microscope. The starch granules of all these substances are quite peculiar in form, and to one accustomed to the use of the microscope the detection of mixtures, &c., would be comparatively easy. Anyone who wished to examine flour, &c., of various kinds in this way ought first to provide himself with samples of the real article, whose purity was beyond doubt, for the purpose of comparison. He should have a sample of pure wheat starch (Fig. 249), pure potato starch (Fig. 250),

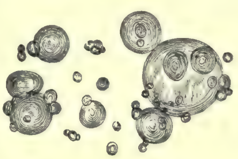

Fig. 249.—Starch Grain—Wheat.

pure Bermuda arrow-root, Canna arrow-root, tous-les-mois (Fig. 251), &c. The differences in the appearances of these different starches are considerable, as the figures show. But careful measurement of the size of the granules is also important, and this can readily be effected by microscopic methods; and finally polarized light is differently affected by different starch grains. A polariscopic apparatus for fitting to a microscope is easily obtained; and thus a complete examination can easily be conducted. By such means the adulteration of flour (Fig. 249) with cheaper potato starch (Fig. 250) is readily detected, and so on; and particles of foreign material, such as sulphate of lime, &c., can also be observed. The flour needs little preparation for examination. A few grains of it, or the arrow-root, or whatever kind of flour it be, are shaken up with a few drops of water in a small clean phial. A drop is placed on the centre of a glass slide and covered with a cover-glass, and then placed on the stage of the microscope. Glycerine is sometimes used instead of water, but it makes the starch granules too transparent.

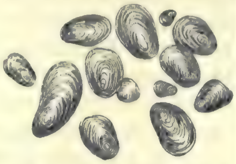

Fig. 250.—Potato Starch Granules.

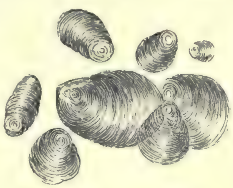

Fig. 251.—Tous-les-mois.

The three accompanying figures (252–254) show the starch grains of three different arrow-roots, the hilum (h) in Fig. 252 being slit-like or conical at the large end of the grain, but less distinct in St. Vincent arrow-root, and still less distinct in Port Natal arrow-root. These granules could not be confounded with wheat flour granules (Fig. 249), nor yet with the granules of potato starch. In the latter the hilum is at the small end of the grain, and the granules are much larger. The two following figures show the granules of bean flour and rice flour, sometimes used as adulterants of wheat flour.

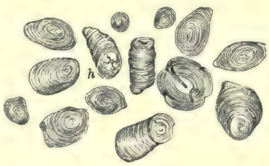

Fig. 252.—Bermuda Arrow-root.

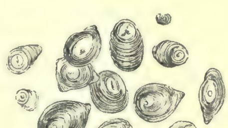

Fig. 253.—St. Vincent Arrow-root.

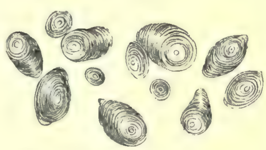

Fig. 254.—Port Natal Arrow-root.

Oatmeal is adulterated with barley-meal, and also with rice and maize; and these adulterations, which, according to Dr. Hassall, are very extensive, may be detected by means of the microscope.

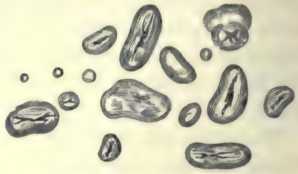

Fig. 255.—Starch Grain—Bean Flour.

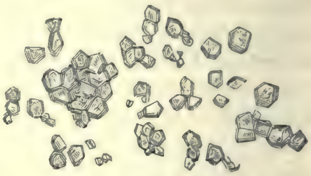

Fig. 256.—Starch Grain—Rice.

Unwholesome Meat.—Good meat, according to Dr. Letheby, possesses the following characters:—1. It is neither of a pale pink colour nor of a deep purple tint, for the former is a sign of disease, and the latter indicates that the animal has not been slaughtered, but has died with the blood in it, or has suffered from acute fever. 2. It has a marbled appearance, from the ramifications of little veins of fat among the muscles. 3. It should be firm and elastic to the touch, and should scarcely moisten the fingers, bad meat being wet, and sodden, and flabby, with the fat looking like jelly or wet parchment. 4. It should have little or no odour, and the odour should not be disagreeable, for diseased meat has a sickly, cadaverous smell, and sometimes a smell of physic. This is very discoverable when the meat is chopped up and drenched with warm water. 5. It should not shrink or waste much in cooking. 6. It should not run to water or become very wet on standing for a day or two, but should, on the contrary, be dry upon the surface. 7. When dried at a temperature of 212° or thereabouts, it should not lose more than 70–74 per cent of its weight, whereas bad meat will often lose as much as 80 per cent. It is also advised to pass a clean knife to the centre of the beef, and smell it after withdrawal, to ascertain if within also the beef is sound.

Very recent observations seem to show that cattle have been long an unsuspected source of disease communication to the people. At Hendon in England and at Glasgow epidemics of scarlet fever seemed undoubtedly to be due to the consumption of milk yielded by cows, suf-

fering from a disease presenting features akin to scarlet fever, as it attacks the human subject. The prevalence of tuberculosis in cattle, and the possibility of tuberculous cattle communicating the disease to human beings, through the medium of the meat of the slaughtered animals, sold for food, have recently occasioned profound anxiety and much discussion among veterinary surgeons. There are perfectly authentic instances on record of meat derived from diseased animals endangering human lives. At the same time there seems no doubt that cattle, which show signs of disease, are regularly slaughtered and sent into market, the owner preferring to do this rather than have the animals dying on his hands. In 1863 Professor Gamgee reported to the privy-council that as much as one-fifth of the common meat of the country was then derived from animals killed in a state of disease. It would, therefore, appear that many of these diseases do not render the meat unsafe for consumption, at any rate after it has been cooked. It is, however, quite possible that, to the eating of such meat is due many simple ailments or states of indisposition, which is not directly attributed to anything in particular. The outbreak of boils and some skin affections have been attributed to the flesh of animals killed when in an unhealthy condition. That there is, nevertheless, great danger in the use of meat obtained from animals suffering from disease of a contagious sort, has undoubtedly been proved. The purchaser has no reliable means of detecting such unwholesome meat. It is only by enlarged powers being given to local authorities, and to thorough and systematic methods of inspection, that this source of danger to the public can be checked.

The presence of parasites in meat, tape-worm of various kinds, and trichinæ, has been referred to at some length on p. 167 and subsequent pages. It is unnecessary to say more on that subject here, unless to call attention to the proof on p. 173 that thorough cooking destroys such parasites, and prevents meat containing them, which has been eaten in ignorance of their presence, from giving rise to any trouble.

Meat in a state of ordinary decomposition is also rightly regarded as unwholesome. Yet it is not nearly universally true that meat becoming decomposed, and even in advanced states of putridity, is hurtful. Game is preferred by the epicure when it is distinctly "high." The North American Indians prefer their meat well advanced in decomposition, and bury it underground to permit it gradually to become so. The Greenlanders treat seal flesh in the same way. Still, meat in a state of decomposition, even slight, is capable of giving rise in many people to severe irritation of the stomach and bowels, acting just like an irritant poison. Putrefaction it has been seen is a very complex process. It is the result of the activity of very many different organisms, each one attacking the meat to derive from it the particular nourishment it needs, and, in the process, producing by-products of peculiar kinds. What we call putrefaction is simply the changes evident to our senses that have been produced, but it is the combined result of many different organisms. It may be that of two pieces of meat, subject to putrefaction, one would be quite harmless, and the other hurtful, though in both the offensive smell, &c., seemed identical, because some particular organism had attacked the one piece and produced in it hurtful materials, not present in the other, whose presence, however, was not discernible by any alteration of odour. For the prevalent view regarding such organisms is that it is not so much the mere presence of the organism that is harmful, but the by-products of their activity. To some of these by-products of the decomposition of albuminous substances the term **ptomaines** has been applied by Professor Selmi of Bologna. It is a remarkable fact that in the course of digestion albuminous foods may yield products hurtful to the person. The fact that some persons cannot eat eggs, mutton, &c., is now partially explained by the view that they are peculiarly susceptible to the influence of certain substances formed during the normal digestion of these foods. The decomposition of fish has been shown to yield a poison, muscarine, which, before that discovery, was derivable only from one of the poisonous mushrooms—*Agaricus muscarius* (see p. 583). From the dead human body various poisons, more or less powerful, have been isolated. A considerable number of cases of sausage poisoning has been recorded, and there have also been several instances of marked symptoms of irritant poisoning after the use of tinned meats. These appear, without doubt, to be due to the presence in the meat of such ptomaines which have been developed as the result of decomposition of some of the albuminous constituents of the meat. It is quite unnecessary to suppose that any poisonous substance has gained entrance, by accident or design, to the meat. Moreover, there is no ordinary test by means of which one could be assured of the wholesomeness or otherwise of the food. The only pre-

caution one can take in buying tinned meats is to notice whether the surface of the tin is hollowed. If it is, one may be sure no decomposition has taken place within, which would be suggested if the tin were to bulge outwards.

Tinned Fruits and Vegetables are not infrequently contaminated by some adulterating agent, added to heighten the natural colour. Thus pickles, olives, green fruit, such as gooseberries, green-gages, and limes, as well as green vegetables, are adulterated with copper, the sulphate of copper, or blue-stone, being usually employed. The quantity of copper present per bottle is said to be as a rule half a grain per bottle. Red fruit—currants, raspberries, cherries—is heightened in colour by decoction of logwood, infusion of beet-root, as well as the red aniline colours. Dr. Hassall states that of 33 samples examined by him, only seven were free from contamination by copper.

To test for copper pour some of the fluid in which the fruit or vegetable is preserved into a tall glass vessel, add three drops of strong nitric acid. Immerse in the fluid for a few hours, a piece of thick, smooth and polished iron wire. If copper be present a fine coating of copper will appear on the wire. If the liquid used is vinegar, as in the case of pickles, it is not necessary to add the nitric acid.

THE DIGESTIBILITY OF FOOD.

In the preceding pages the value of food-stuffs has been considered from the chemical point of view mainly. We have seen that, for the nourishment of the body, substances containing nitrogen in the form of albuminous bodies, such as the white of egg, the casein or curd of milk, the myosin of flesh, the gluten of wheat, and the legumin of peas and beans, and carbon in the form of sugar, starch, and fat, are necessary, and that upon the quantities of such substances contained in the various food-stuffs does their nutritive value depend. But it is very necessary to consider foods from another point of view. These food-stuffs become valuable only when they have passed into and become part of the circulating blood in our bodies. This they cannot do in the condition in which we eat them, hence the elaborate apparatus and process of digestion, described in section VI. in the first part of this work, to fit them for entering and becoming part of the blood. This process requires time and implies the doing of work by the digestive organs—that is to say, the expenditure of energy. Now it is plain that if one substance takes a longer time and more work of the bodily organs to undergo digestion, more energy will have been expended in the process, and, before one could quite accurately judge of its value to the body as food, one would require to deduct from the total nutriment it was calculated to contain, a quantity representing the energy expended in its digestion. So that another substance, containing less nutritive material, might be actually more profitable to the body, because more easily and rapidly digested. The time, therefore, the various food-stuffs require in order to undergo digestion requires to be taken into account in estimating their relative values. In the next place one must consider how far each substance can yield up to the body the nutritive material which chemical analysis shows it to contain, whether it is in such a form, that is to say, as renders it suitable for the action of the digestive fluids rendering it fit to enter the circulation. If the nutritive material it contains cannot readily be extracted from it by the process of digestion, much of it will never really enter the body, but will simply pass through the alimentary canal unchanged, and be finally cast off as waste from the bowels. If the quantity of waste, so cast off after different diets, be measured, a fairly accurate idea of the actual amount of nourishment each diet has supplied to the body will be obtained. In determining the digestibility of foods, then, these two things require to be taken into account, the time required for their digestion, and the actual amount of each rendered available for purposes of nutrition. When these have been ascertained, and when this knowledge is added to that of the chemical composition of the various foods, one has the chief information necessary for the forming of a judgment as to the values of the different foods.

The Time required for Digestion of different substances is our first consideration. There are several ways of acquiring this information. As is indicated in section VI. Part I., the ferments, which are the active agents in digestion, can be separated out from the organs of the body in which they are prepared. The ptyalin of the saliva (p. 143), the pepsin of the stomach juice (p. 143), the pancreatin of the pancreas (p. 145), are readily obtained in quantity. One may take a solution of white of egg, a solution of boiled starch, and so on, place some in a test tube, add to it a small quantity of the digestive ferment, pepsin, pancreatin, &c., and then set it aside in a place kept at the temperature of the

body, and note what time elapses before the food-stuff has been completely acted upon by the ferment. Such experiments, made with different substances, under precisely similar conditions, will enable one to determine the relative speed of digestion of the different substances. A unique opportunity of observing the rapidity of digestion in the human subject, under ordinary conditions, was afforded to Dr. William Beaumont, in the person of one Alexis St. Martin, a Canadian, who had a permanent opening into the stomach through the skin, owing to a gunshot wound. Dr. Beaumont was able to introduce substances into the stomach through the opening and observe the rate of digestion. More recent experiments have been made in German laboratories, where students, laboratory attendants and others, willingly lent themselves for the purposes of observation, by taking food into an empty stomach, and, after varying times, allowing it to be withdrawn by a stomach-pump, so that the extent to which it had been acted upon might be determined. In various other ways much knowledge has been obtained.

The following list from Beaumont indicates the time of digestion *in the stomach* of various animal foods:—

Name of Food.	How Cooked.	Time.
Pigs' Feet (pickled), ...	Boiled ...	1 hour.
Tripe (pickled), ...	,, ...	1 ,,
Eggs (whipped), ...	Raw ...	1½ hours.
Salmon Trout (fresh), .	Boiled ...	1½ ,,
Barley Soup, ...	,, ...	1½ ,,
Venison Steak, ...	Broiled ...	1 hour 35 min.
Milk, ...	Boiled ...	2 hours.
Beef Liver, ...	Broiled ...	2 ,,
Eggs, ...	Raw ...	2 ,,
Cod (cured, dry), ...	Boiled ...	2 ,,
Milk, ...	Raw ...	2 ,, 15 min.
Turkey Eggs, ...	Boiled ...	2 ,, 25 ,,
Turkey, ...	Roasted ...	2 ,, 30 ,,
Sucking Pig, ...	,, ...	2 ,, 30 ,,
Lamb, ...	Broiled ...	2 ,, 30 ,,
Meat and Vegetable Hash, ...	Warmed ...	2 ,, 30 ,,
Chicken, ...	Fricassed ...	2 ,, 45 ,,
Custard, ...	Baked ...	2 ,, 45 ,,
Beef, ...	Boiled ...	2 ,, 45 ,,
Oysters, ...	Raw ...	2 ,, 55 ,,
Eggs, ...	Soft boiled.	3 ,,
Beef-steak, ...	Grilled ...	3 ,,
Mutton, ...	Boiled ...	3 ,,
Bean Soup, ...	,, ...	3 ,,
Chicken Soup, ...	,, ...	3 ,,
Oysters, ...	Roasted ...	3 ,, 15 min.
Pork Steak, ...	Grilled ...	3 ,, 15 ,,
Flounder, ...	Fried ...	3 ,, 30 ,,
Butter, ...	Melted ...	3 ,, 30 ,,
Cheese (old strong), ...	Raw ...	3 ,, 30 ,,
Mutton Soup, ...	Boiled ...	3 hours 30 min.
Eggs, ...	Hard boiled	3 ,, 30 ,,
Salmon (salted), ...	Boiled ...	4 ,,
Fowls, ...	,, ...	4 ,,
Soup, Beef, Vegetables, and Bread,	,, ...	4 ,,
Heart, ...	Fried ...	4 ,,
Marrow Bone Soup, ...	Boiled ...	4 ,, 15 min.
Pork (recently salted),	,, ...	4 ,, 30 ,,
Veal, ...	Fried ...	4 ,, 30 ,,
Wild Duck, ...	Roasted ...	4 ,, 30 ,,
Mutton Suet, ...	Boiled ...	4 ,, 30 ,,
Pork, ...	Roasted ...	5 ,, 15 ,,
Beef Suet, ...	Boiled ...	5 ,, 30 ,,

The time of digestion of vegetable foods is shown in the next table:—

Name of Food.	How Cooked.	Time.
Rice, ...	Boiled ...	1 hour.
Apples (sweet mellow),	Raw ...	1 ,, 30 min.
Sago, ...	Boiled ...	1 ,, 45 ,,
Tapioca, ...	,, ...	2 hours.
Barley, ...	,, ...	2 ,,
Apples (sour), ...	Raw ...	2 ,,
Pod Beans, ...	Boiled ...	2 ,, 30 min.
Parsnips, ...	,, ...	2 ,, 30 ,,
Potatoes (Irish), ...	Roasted ...	2 ,, 30 ,,
Cabbage (head), ...	Raw ...	2 ,, 30 ,,
Apple Dumpling, ...	Boiled ...	3 ,,
Corn Cake, ...	Baked ...	3 ,,
Corn Bread, ...	,, ...	3 ,, 15 min.
Carrots, ...	Boiled ...	3 ,, 15 ,,
Bread (wheat, fresh), .	Baked ...	3 ,, 30 ,,
Turnips, ...	Boiled ...	3 ,, 30 ,,
Potatoes (Irish), ...	,, ...	3 ,, 30 ,,
Green Corn and Beans,	,, ...	3 ,, 45 ,,
Beets, ...	,, ...	3 ,, 45 ,,
Cabbage, ...	,, ...	4 ,,

The times given in these tables are the mean times in the case of the particular individual experimented on, and are not to be taken as absolute, though they fairly indicate the relative digestibility in time of the different substances. In the case of that one individual the time required for digesting the same substances varied on different days with varying conditions of the person himself, and with varying external conditions also. Thus the rapidity varied with the quantity eaten. A full meal was digested even more readily than a small and insufficient one, though, as one would expect, excess of food slowed the process. The rapidity varied also with the nature and amount of previous exercise, and with the interval since the preceding meal. After prolonged and exhaustive exercise the digestive organs share in the general depression, and food ought not to be immediately taken; while, if too short an interval has elapsed since the last meal, the next one finds the stomach unprepared to receive it. In the

case of St. Martin the state of the weather was found to affect the rapidity of digestion. Active exercise immediately *after* a full meal tends also seriously to interfere with the digestive process, and even to arrest it. If the meal has been small, moderate exercise facilitates its digestion, and moderate exercise is also of advantage some time, an hour or so, after a full meal.

Somewhat conflicting views are held as to the influence of sleep after a meal, many maintaining that the after-dinner nap, customary with many people, interferes with the rapidity of digestion. It is unwise to lay down hard and fast rules. It is an undoubted fact that a sleep after dinner is useful to many, though it may be injurious to others. It may be said with some confidence that a sound and prolonged sleep is hurtful, because in sleep the activity of the vital processes is diminished, and this, lasting for any time, would undoubtedly retard digestion. It may be taken as a general rule that after a full meal, such as dinner, it is better to pass an hour or more in pleasant conversation, or some similarly light occupation, before any active work is engaged in. After lighter meals, such as lunch, tea, &c., no such interval is required.

Dr. Beaumont found that cold drinks introduced into the stomach in any quantity during digestion had a markedly slowing influence upon the process. A single gill of water at 50°, introduced on one occasion, lowered the temperature within the stomach to 30°, and its natural heat was not restored for half an hour. Drinking iced water, or cold fluids in any quantity, eating of ices after meals, &c., are therefore not to be encouraged.

One extremely important factor in the rapidity of digestion of solid food is the degree to which it has been broken down by chewing. If the food be imperfectly chewed, it remains in large pieces, and the gastric juice cannot penetrate to the interior of the masses; whereas if the food has been broken up into minute portions, they are all attacked at once, and digestion is rapidly completed. Probably this supplies the reason of the greater rapidity of digestion of boiled over unboiled milk. In the process of digestion milk curdles, the curd forming masses of considerable size, which take some time before they are broken down by the gastric juice. If the milk has been boiled, the curd formed is in much smaller masses, and hence the greater ease in digestion.

As regards the actual time taken by some of the substances, the above table will occasion some surprise by the length of time assigned to soup for its digestion. Barley soup digested in 1½ hours, but bean soup and chicken soup took as long, 3 hours, as grilled beef-steak and boiled mutton, while mutton soup took half an hour more, and bone soup 1¼ hours longer. Contrary to one's expectation soups and fluid diet are not more easily digested than solid nutriment. This is confirmed by the experience of invalids, convalescents, and dyspeptic persons, who very frequently prefer a solid or semi-solid diet to the beef-teas and chicken broths which are the popular diets for them. Dr. Beaumont says that "solid food is sooner disposed of by the stomach than fluid, and its nutritive principles are sooner carried into the circulation." It has been observed, however, that the exhaustion from abstinence is more quickly removed by liquid than by solid nourishment. On the whole animal food, when suitably cooked, is more easily digested than vegetable food, in particular than green vegetables.

The Influence of Cooking on the Rapidity of Digestion is well shown in the tables that have been given.

Raw whipped Eggs digested in		1½ hours.		
Raw Eggs (ordinary)	,,	2	,,	
Soft boiled Eggs	,,	3	,,	
Hard ,,	,,	3	,,	30 min.

The whipped eggs were digested most readily, because by the whipping process the egg was worked up into a froth, that is, the egg was separated up into minute particles by the switching in of air, and the digestive fluids attacked it most easily. The heating process coagulates or clots the chief constituent of the egg, and renders it no longer soluble in water. The longer it is boiled the more insoluble it becomes, and the longer is its period of digestion. This is worthy of noting, because a similar change is produced in the albuminous substances of butchers' meat by cooking. If the meat is subject for any length of time to a heat as great as that of boiling water, all its albuminous material becomes changed into the insoluble form, and its readiness of digestion is consequently much diminished. This is very well shown in the case of experiments performed by Jessen, at Tübingen. The subject of the experiments was a laboratory attendant. He took meat, raw or cooked in various ways, and after the lapse of varying times allowed it to be withdrawn by means of a stomach pump to determine the rapidity of digestion. The different kinds of

meat were all taken on an empty stomach, so that no disturbance could arise by the presence of other foods. In this case the following were the results:—

Raw Beef digested in	... ...	2 hours.
Boiled Beef (half done) digested in		2½ ,,
Boiled Beef (well done)	,,	3 ,,
Roasted Beef (half done)	,,	3 ,,
Roasted Beef (well done)	,,	4 ,,
Raw Mutton digested in	...	2 ,,
Raw Veal	,, ...	2½ ,,
Raw Pork	,, ...	3 ,,

This shows that the more thoroughly meat is cooked, the longer is the time required for its digestion. Raw or half-raw meat is therefore preferable to well done meat. But then there arises the risk of being supplied with meat containing the eggs of intestinal worms (see p. 167), which thorough cooking would render harmless (see p. 173). Vegetable foods, however, require cooking for their digestion, and thorough cooking. The cellulose, which envelops starch grains and invests vegetable cells, is not soluble in the digestive fluids. By the process of cooking it is ruptured, and the contents of the cellulose envelope are therefore allowed to come into contact with the digestive juices.

Aids to Digestion in the shape of condiments, mustard, pepper, and alcoholic stimulants are much in use for accelerating the digestive process. Experimental physiology offers a few results in the direction of justifying an opinion on this subject also. It appears from sundry experiments that, in health, these adjuncts are not necessary. In one or two of the trials all flavouring materials were removed from the food before it was given. It was thus rendered tasteless and insipid, and was eaten without relish, indeed with distaste and almost repugnance, by the person, and yet its digestion was not impeded. In the case of the healthy, therefore, only the milder kinds of flavourers or appetizers ought to be used. On the other hand, in the case of those of small appetite or feeble digestion, there is no doubt such appetizers are valuable, not only because of the fillip which they give to the appetite, but also because, by their stimulating action on the mucous membrane of the alimentary canal, they excite increased flow of blood to the part, and increased secretion of digestive juices, with consequent increase of the digestive capacity. But the risk of healthy persons, who need no such goads to digestive activity, employing such agents, from liking, to excess, ought to be guarded against. If the stomach is accustomed to pronounced exciting to its work, by and by it will refuse to act till the stimulus is applied.

The Influence of Tea, Coffee, Whisky, &c., on the Time of Digestion has recently been studied by Sir Wm. Roberts of Manchester. He carried out his observations by means of test-tubes containing, some of them solutions of starch, others of them morsels of beef, &c. To these he added the digestive ferment, and observed how long the process occupied in the test-tube, kept at a proper temperature. To a test-tube with exactly the same ingredients, he added a definite quantity of infusion of tea, or coffee, or whisky, &c., as the case might be, and contrasted the rapidity in this case with that of the preceding.

In the case of the digestion of starch he found that a 5-per-cent infusion of tea arrested starch digestion when it amounted to 10 °/₀ of the total contents of the test-tube. That is tc say, if the contents of the test-tube consisted of tea infusion to the extent of a tenth, digestion stopped. Even if the tea infusion was only a hundredth part of the contents of the test-tube, the digestion of the starch was slowed. *This injurious effect of tea, Roberts found, was prevented if* 10 *grains of bicarbonate of soda* (*the quantity that can be taken up on a threepenny piece*) *were added to each* 10 *ounces* (*that is half a pint, or a breakfast-cupful*) *of tea.* Coffee had not the same effect to the same extent, for double the quantity of a 5-per-cent infusion of coffee did not affect the action on the starch to the same extent.

The digestion of starch was slowed by 10 per cent, and quite stopped by 20 per cent of French brandy, while it took twice the quantity of Scotch whisky to produce the same effect. This action was due not to the spirit, but to the ethers and volatile oils contained in the brandy and whisky, and more in the former than the latter. In the case of wine 1 per cent was sufficient to arrest digestion, because of the acidity of the wine. If to sherry or port something be added to counteract the acidity, such as effervescing soda, potash, or seltzer water, or Apollinaris, the slowing action is prevented. Simple aerated water will not do: it must contain some alkali, like soda or potash, in solution.

Roberts extended his experiments to digestion as carried on in the stomach, and found similar results. Tea and coffee both seriously delay digestion there, and so also does cocoa, though not to the same extent as either of the former. Twenty per cent of a 5-per-cent infusion of either tea or coffee seriously slowed

the process, while a quantity equal to ten per cent had a perceptible effect.

In the case of alcoholic liquors it was found that, if the total amount added to the food was not sufficient to make the quantity of proof spirit more than equal to a tenth of the total bulk of the food, no retarding effect was observed; when the quantity reached 20 per cent—was a fifth, that is to say, of the total bulk of the food—the slowing effect was slight; and when it reached 40 per cent almost no digestion occurred. Roberts estimated that if the total quantity of food taken into the stomach at a meal weighed 2 lbs., then 2 ounces of brandy or whisky—that is, less than a wine-glassful—would equal five per cent, and would not impede digestion. But if the quantity of spirit were increased, the delay of digestion would set in, in proportion to the quantity of alcohol above the 2 ounces taken. Sherry slows digestion to an extent out of all proportion to the spirit it contains, a quantity equal to a fifth of the total bulk of food taken making the time needful for digestion three times longer than it ought to be; while double that quantity altogether stopped it. Sparkling wines were less injurious than still wines. Malt liquors also impede the process, and, like wines, to an extent quite out of proportion to the contained spirit. When the malt liquor reached to 40 per cent of the bulk of the food, the deterrent action was very marked. If, then, malt liquors, such as stout, are taken with dinner for the sake of their stimulating effects, specially in the case of invalids, a much smaller quantity than the customary pint bottle yields should be used. It will very frequently be found that a third of that amount is useful without impeding digestion. Hence the value of the ½-pint bottles now coming into use for the various kinds of nourishing or "invalid stout," as it is called.

The Quantity of each Food-stuff extracted in the body for purposes of nutrition must next be considered. This is determined by weighing the quantity of food eaten, and then weighing the waste cast off from the bowel. The difference represents the amount of food retained in the body for use. Though two foods contain the same amount of nutritive materials, but one of them invariably yields more waste, it is evident that that one is of less value; it is, that is to say, less digestible. A considerable number of experiments has been made in this direction, chiefly in German laboratories; and the results are summarized in the following table. In each case the calculation is made for 100 parts of the food-stuff, and in one column is shown the proportion of that retained in the body, and in the other the proportion expelled as waste.

Name of Food.	Proportion Used in Body.	Quantity Expelled.
Sugar, ...	100	0
Butter, ...	98	2
Oleo-margarin, ...	96	4
Rice, ...	96	4
Fish, ...	95·1	4·9
Maccaroni, ...	95·7	4·3
Roast Beef, ...	94·8	5·2
Hard-boiled Eggs, ...	94·8	5·2
White Bread, ...	94·4	5·6
Milk and Cheese (in proportions of 11 of former to 1 of latter), ...	94	6
Indian Corn, ...	93·3	6·7
Milk and Cheese (9½ to 1), ...	93·2	6·8
Cow's Milk, ...	91	9
Pease Meal, ...	90·9	9·1
Potatoes, ...	90·6	9·4
Rye Bread, ...	89·9	10·1
Milk and Cheese (2 to 1), ...	88·7	11·3
Cabbage, ...	85·1	14·9
Coarse black Rye Bread, ...	85	15
Carrots, ...	79·3	20·7

Putting sugar and butter aside as being used only as adjuncts to food, we find that rice, meat, and eggs (and fish is included with meat) head the list of digestible articles, practically yielding up almost all the nutriment they contain to the body. Of bread it is interesting to note that the quantity of nutriment extracted depends on the fineness of the flour. Thus rye bread is far behind white bread, and the coarse black bread still further. We have here an illustration of the fact commented on on p. 560, that though the branny portions of the wheat-grain contain more tissue-forming material than the white kernel, their addition to the flour to any extent does not make the bread more valuable, both because these coarser particles are less digestible and because they so stimulate the bowel as to hurry the material too fast along the alimentary canal. As regards milk it is very interesting to observe that there is less waste on an exclusively milk diet in the case of the infant than in the case of the adult. Thus in the case of a child, observed for 11 days, 6·35 per cent of the dry solids of the milk were expelled daily from the bowel, while in the case of the adult the amount varied from 7·8 per cent to 10·2 per cent. This is another proof of what has already been said on p. 542, that as an exclusive diet milk is more suited for the growing than for the full-grown person. In the adult a considerable proportion of the waste consists of the mineral constituents of the milk, particularly the lime

salts, which the child retains for the formation of bone. In short, cow's milk is not so advantageous a diet for the adult as meat or egg. The experiments made with milk and cheese were so performed because cheese could not be made an exclusive diet. It may seem remarkable that milk with a small proportion of cheese should be more completely made use of than milk alone. The reason seems to be that milk alone forms large masses of curd in the stomach, in process of digestion, which the gastric juice cannot quickly attack, while, if cheese has been eaten, the small particles prevent the curd forming in such masses, and permit of the gastric juice attacking a large number of smaller portions of curd at the same time. If the proportion of cheese rises unduly, then it is not so completely digested. Then it is to be noted how much more digestible the animal foods are than those vegetable foods which are rich in proteids or tissue-forming materials, such as peas, beans, &c. If animal food is to be entirely replaced by vegetable food, it must be by such foods as peas, beans, and lentils, for these only contain a rich supply of the needful proteid. The table shows that such replacement would not be economical of the energy of the body. As regards fat, though the table is silent on that point, it appears that animal fat is more digestible than vegetable fat, and more easily assimilated.

Such considerations do not countenance the use of vegetable foods to the exclusion of animal foods. They rather support the view that an appropriate mixture of the two kinds of food-stuffs will most readily yield the desired quantity of nutriment to the body, with the greatest economy of bodily energy, and corroborate the position taken up in the early part of this section, that, for growth and repair of tissues, material is most readily and abundantly yielded by animal foods, and for yielding of energy for the maintenance of heat and the doing of work the material is most easily obtained from the vegetable kingdom.

THE PRINCIPLES OF COOKING.

Why do we cook? is a question which would probably puzzle a great many people who pride themselves on their skill in the art of cookery, but it is a question on which really depends the answer to the other question, *How* should we cook? Probably, in the first instance, the object of cookery is to please the palate, so that eating shall not be simply a necessity of continued existence, but also an ever-recurring source of pleasure and gratification. But a second and very important object in cooking is to render the food to be eaten more readily digestible. The immediate purpose of eating is to satisfy the demand for material for the upkeep of bodily strength and vigour, and it is evident that the success of cookery and its methods are to be judged by the extent to which it aids that purpose and adds pleasure to it, while any method is self-condemned which renders the task of extracting the nutriment from the food more difficult for the body, even though it, at the same time, adds greater pleasure to the taste. These two main objects of cooking are of very great importance for all classes of the population. There is far too great a tendency to regard what is called, with some suspicion of a sneer, the "gratification of the palate" as an object which can only be followed by the moderately "well-to-do people," and as a consideration which the poorer of the community cannot afford to regard. As an absolute matter of fact it is a subject of more importance to those of limited means than to those of large resources. It has been shown that the flavour of a meal has not any influence on its digestion in the case of a healthy man. But the same experiments which proved this proved also that the absence of flavour was a serious hindrance to the taking of a proper quantity of food. Thus Prof. Forster observes that in the case of one man, on whom he experimented, meat from which the flavour had been removed was so tasteless as to be eaten in any considerable quantity only with difficulty, and yet the quantity digested and passed into the circulation was as large as with the same meat roasted in the ordinary way; and in other experiments with a mixed diet, from which also the flavour was removed, the diet became, when continued, so repugnant that great effort was required to eat it, while, nevertheless, the digestion was unaffected. Now in the case of those with limited means the diet is apt to be, indeed is certain to be, much more restricted in variety, and its sameness will in time produce something of the same aversion. In such cases the art of cookery has greater scope, and becomes of infinite value by the variety it may introduce without additional expense, and its benefits will be far more marked than in the case of those whose means permit of a greater variety of food-stuffs. The poorer classes have, indeed, more need of knowledge being put within their reach of the method of gratifying the palate by the art of

cooking than the richer classes. There can be little doubt that the temptation among the working-classes to the frequent use of stimulants is greatly strengthened by the lack of variety and excitement in the food habitually served up to them, and that the introduction among them of better and more extensive methods of cooking would have a direct and powerful effect in the promotion of temperance. It would also add to their material resources by showing them how simple and inexpensive articles, remnants of former meals, and so on, might be dressed up in agreeable and appetizing and satisfying forms. For it has been shown by actual statistics that there is no class of the population which buys so expensive kinds of food—the richest cuts of beef, for example—all to obtain the richness and strength, which they think is associated with the fuller flavour, and which they might confer on the food more cheaply by modes of preparation.

Cooking has very different effects on animal food from those it produces on vegetable food. It has been shown in the preceding article that, as a rule, animal food is considerably more digestible in the raw than in the prepared state, while the chief vegetable foods, such as bread, oatmeal, rice, corn-flour, green vegetables, &c., are made digestible only by sufficient cooking. On the other hand the flavour of both is largely the result of the method of preparation. In the case of animal foods, in particular, the question thus comes to be, How may it be cooked so as to develop its finest flavour, without unduly diminishing its digestibility?

Let us take, as an example, a piece of beef or mutton. The nutritive material it contains is chiefly the proteid or albuminous constituent, which forms the chief part of the red flesh. This is largely soluble in cold water, and is in that form easily digested. But by water near to the boiling point, or by heat to the same degree, however applied, it is coagulated and rendered insoluble and less easily digested, and the greater the heat and the longer it is applied the more solid becomes the coagulated mass, and the more difficult does it become of digestion. The connective tissues or fibrous portions which bind the red flesh together, and also form the tendinous parts, are converted into gelatine by boiling, and are rendered more easily broken down, so that the mass of meat can be more easily broken down into particles, can be more easily chewed, and therefore more readily prepared for the action of the digestive juices. To this extent, therefore, cooking will aid the digestion of animal food. The flavouring materials, the extractives of the meat, are dissolved by water, and in process of cooking with water may readily be dissolved out to a large extent, rendering the meat more or less tasteless. Moreover the action of the heat develops flavouring substances in the meat not existing in it previously as such. The nature and extent of these sapid substances entirely depend upon the manner in which the heat is applied. They are specially developed by a dry heat, as applied in roasting, and it is owing to their production that roast beef is so much more full in flavour than beef cooked otherwise. It appears, then, that the cooking of a leg of mutton is a much more complicated problem than many people suppose. For the desire is (1) to apply the heat long enough to heat it equally throughout, and to render it as tender and easily masticated as possible, (2) to guard against extracting from it any of the flavouring materials it already possesses, (3) to develop as much as possible new flavouring substances, and withal (4) to avoid so great a degree of heat, or so long continued an application, as would harden the flesh and render it difficult of digestion. These are the different points to secure which a cook really aims, when a leg of mutton or a roast of beef is set him to prepare, whether he would express them in so many words or not, and they clearly indicate a particular method to be adopted.

But now suppose the same cook has a piece of beef or mutton set before him for the making of soup. His object is now very different; it is no longer to retain in the meat as much of its flavouring materials and juices as possible, but to extract them, and to get as much of them as he can into the surrounding water; and his method must be correspondingly different. If one clearly realizes to one's self the difference between these two processes, and the difference of method they imply, then one shall have laid a sure foundation for the practice of cookery; but every one who has not realized them is ignorant of the very A B C of the science. Let us consider the two cases.

To extract the juices of meat is easy enough, unfortunately too easy, many people will say, and too often done. All one requires to do is to steep the beef in cold water, and, particularly if it has been broken down into small pieces, all of its flavouring material and a considerable quantity of its nourishing material will become dissolved in the water. But how to retain the juices in the meat is the problem. Suppose the leg of mutton to be plunged into boiling water,

what will happen? Almost immediately the albuminous portions of the meat in contact with the boiling water will become insoluble, will coagulate, and if the meat be exposed to this heat for a short time only, it will have become completely surrounded by a film of coagulated material, the heat not having had time to penetrate far in—will have become sealed up as it were; and if the mutton were now placed in cold water, this coagulated film, being insoluble, would oppose the passage outwards of the juices of the meat. If the meat were kept in the boiling water the heat would gradually penetrate inwards, coagulating and hardening as it proceeded, the outer parts becoming always harder and drier because of the prolonged action of the high temperature. But if, after the meat has been two or three minutes in the boiling water, the heat of the water is allowed to fall considerably, then a film of coagulated albumin will have formed outside sufficient to retain the juices of the meat, and the cooking can be proceeded with at a lower temperature and a longer period without risk to juiciness and tenderness. Exactly the same principles are applicable in roasting or baking meat. One desires to cook the meat throughout to a certain degree, but to retain all the juice within it. If it is exposed suddenly, and all round, to the full influence of a bright clear fire, a film of coagulated albumin is formed, sealing up the juices; then the meat is withdrawn from its close proximity to the fire, or if it be in an oven the heat of the oven is allowed to fall, and cooking gradually proceeded with.

Boiling, roasting, baking, broiling and frying are the chief ordinary operations in the preparation of food, and these may now be briefly noticed in detail.

Boiling. What has been already said in general is specially applicable to boiling. In boiling the heat is communicated to the meat by the agency of water, and, except in the production of soups and beef-teas, and the like, one desires to convey as little as possible of the material of the meat to the medium of communicating the heat. To cook meat by this means, therefore, which is to be served up at table, the water should be boiling, the meat plunged into it, there being sufficient water completely to cover the meat, and the pot should be kept on the fire till the water again boils. The introduction of the meat will have put it "off the boil" for a few minutes. When the water has boiled again for two or three minutes, not more, the pot should be removed to the side of the fire, so that the temperature of the water is reduced to below even the simmering point. If one were to gauge the temperature by means of a thermometer, it would be not more than 180° Fahr., or between that and 160° Fahr. (boiling point is 212°). At this heat it should be kept till the central parts of the meat have had time to be heated to the same degree. The time necessary will depend, of course, on the size of the piece of meat, and it will be longer than if the boiling temperature were maintained; but the reward of the longer period is juicy meat, tender, and with its fibres soft and readily separated from one another, not firm, tough, and shrunken. In thus cooking meat a fork should never be plunged into it to see if it is sufficiently done, for this would break the sealing and open a way of escape for the retained juices. Meat when thus properly cooked is easily recognized at table by the rush of juice as soon as it is cut.

Fish should always be boiled in this way, with skin as unbroken as possible; and their flavour is still better obtained if the water used is hard, if sea-water is used, or if some salt is added to fresh water.

In the case of eggs the same method produces excellent results. They are commonly kept in boiling water for three minutes or so. The white becomes exceedingly firm and indigestible, specially next the shell, and often the yolk is unaffected. Now if the eggs be plunged into boiling water and immediately removed from the fire altogether, but allowed to remain covered up in the water for ten minutes, the white will not be hardened, but nicely jellied, and the yolk just set. This is the condition in which eggs should be eaten. This is called "coddling eggs;" and while it may be done in a small covered pan, it may also be done on the breakfast table by means of an appropriate vessel. A tin vessel is obtained so deep that when half full of water an egg would be completely immersed. It may be made of any diameter one pleases, according to the number of eggs one may have to cook in it. It should have a tight-fitting lid, and should be embedded in a "cosy" made for it. A cover should also be made for the lid, so that the whole vessel is surrounded by a cosy. The boiling water is poured into the pan, $\frac{1}{2}$ pint for 1 egg, $\frac{3}{4}$ths of a pint for 2 eggs, and 1 pint for 3 eggs, and the eggs immediately placed in the water, the lid secured, and the whole covered up. This can lie on the table, and the water and eggs are introduced 10 minutes before the breakfast is served. If a few minutes' delay

occurs the eggs are not overdone, and they are kept hot for a long time.

For the production of broth, and when it is desirable to extract all the possible ingredients of the meat, a high temperature is not necessary at any time. The meat should be reduced to small pieces, placed in cold water for some time, slowly heated, but never to the boiling point, for even before that high temperature is reached the albuminous constituents which have become extracted will be coagulated and separated out, but will remain in solution if a lower temperature is maintained. When it is desired to produce stock from tendinous meat, such as hough or joints of bone, prolonged boiling is necessary for the extraction of gelatine, which is derived from tendons, gristle, &c., by boiling.

The flesh of young animals, veal and lamb, does not stand boiling well, because of the large amount of gelatine-yielding substance present, the dissolving out of which makes the meat fall to pieces.

Boiling is the method of preparation most suitable for invalids and those of weak digestion, but it develops the flavour of meat much less than either roasting or stewing, and is not so much enjoyed. Boiled meat is more easy of digestion than that cooked in any other way (see p. 603).

Roasting has already been referred to. The meat ought at first to be brought close to a bright clear fire till the surface is coagulated to retain the juices, then it ought to be withdrawn to such a distance that the heat can never rise above 180°, and it is then allowed gradually to cook throughout. The dry heat causes a considerable loss by evaporation of water, and, to prevent this going on unduly, basting is resorted to by the use of melted butter or the dripping caught in the pan. Not only does this prevent drying but it aids the browning of the outside of the meat, and it is by this browning that the peculiarly acceptable flavour of roast meat is produced.

While roast meat is not so digestible as boiled, it is more acceptable as a rule, because of the increased flavour, and next to boiling, it is most suitable for invalids and dyspeptics. The fat of the meat undergoes some amount of chemical change because of the prolonged action of the heat, and fatty acids are produced which are the chief cause of some tendency to disagree with persons of weak digestion.

Broiling or **Grilling** is practically the same as roasting in its effects. The cooking on the grill is done with great rapidity, a hot clear fire being necessary. The grill being brought close to the fire at first and rapidly turned, the whole surface of the meat is sealed. The grill is then removed to a little distance, and the interior portion of the meat is done more slowly, being cooked in its own juices, as it were, within the outer crust that has been formed. This is an excellent method, when well done, for cooking a chop or steak, and produces a very savoury dish, little less digestible than by boiling.

Baking is pretty much the same as roasting, but being done in the confined space of the oven, partly by hot air, there is less of the material of the meat driven off as vapour in the process. Consequently the flavour produced is much richer and fuller than in roasting. On that account baked meats are much less digestible than roasted, and had better be avoided altogether by the dyspeptic.

Frying is an excellent but much-abused method of cooking. The common method of frying is by the use of the ordinary shallow frying-pan, and the meat is kept from sticking to the pan and burning by some melted butter, lard, or dripping. Now this suits well enough for meat cut in very thin slices such as ham, which can be kept fairly well covered with the liquid fat, or for eggs or omelettes, but is entirely unsuited for other kinds of meat. What is properly meant by frying is cooking in oil, in which the oil is made the vehicle for communicating the heat to the meat, just as water is the vehicle in the case of boiling. This requires a deeper vessel than the ordinary frying-pan, capable of holding such a quantity of fat as will permit of the meat being completely immersed. Now fat boils at a temperature very much higher than water, indeed cannot be boiled in an open pan at all, so that long before its boiling point is reached the temperature of the liquid fat is far above the highest temperature obtainable with water, namely, 212°. Lard is commonly used, and when it is put into the pan and kept on the fire for some time the liquid fat bubbles and crackles as if it were boiling. By and by it becomes quiet. It has not been boiling: it has reached the temperature of boiling water, and then any water contained in the fat is driven off as steam, causing the commotion. When all the water has been evaporated the surface of the liquid becomes still, and the temperature of the fat is then considerably above 212°. Its temperature continues to rise, and soon if bread crumbs be dropped into the fat they at once become browned. At this stage

the meat may be introduced. The cutlet or chop is usually covered first with a coating or batter of switched eggs and bread crumbs, and then dropped into the oil, so as to be completely covered by it. If the fat is sufficiently hot the chop or cutlet is cooked in about 10 minutes, very equally throughout, and the coating has acquired a delicate brown with a crisp feeling and pleasant flavour. The hot oil in contact with the outside of the meat has coagulated the albumin, the continuance of the heat has raised the interior of the meat to the boiling point, and it is cooked by the heat of its own juice. Above the boiling point the heat of the meat cannot rise so long as it contains any juice, and the juices are retained. The result is that if the time be properly gauged the meat is well cooked, juicy and tender. The spitting and hissing noise produced when the meat is introduced is due to the explosion of little globules of steam, produced by contact with the hot oil. Further, owing to the very heat the oil is prevented passing into the meat, and when it has been removed and the surface oil allowed to run off, no trace of fat is left. Now this is not an expensive method of cooking, for there is actually less fat used than with the ordinary frying-pan. The fat is readily purified for use again by pouring it, still hot, into a vessel of water. The impurities sink into the water; the fat floating, is easily removed when cold. Besides pure lard, cotton-seed oil (p. 591) may be used. It is, when obtained pure, an excellent oil for the purpose, of very agreeable and delicate flavour, and has the advantage of being much cheaper than lard. This is the only proper method of frying; and when chops, cutlets, and fish are so cooked they are not only pleasant in flavour but also not difficult of digestion. The ordinary shallow frying-pan, on the other hand, is destructive to the meat cooked in it. The meat is really dried, hardened, and shrivelled, and its digestibility very seriously impaired. The use of such a pan ought to be limited to the cooking of omelettes, pancakes, and such like.

Stewing is a process whose object is entirely different from that of the methods already described. Little or no water is added to the meat in the stew-pan. *The meat is never raised to the boiling temperature.* The juice of the meat is thus allowed to exude, and additional liquid is obtained from the various herbs, vegetables, &c., mixed with the meat. A rich full-flavoured gravy is thus obtained in which the meat becomes cooked. Now in the ordinary stew-pan the difficulty of keeping the heat at a proper level is very great, because the meat is directly in contact with the vessel on the fire. As a result a boiling, or, what is next to it, a simmering temperature, is communicated to the meat, which is thus toughened and shrunken by the firm coagulation of its albuminous constituents. If, however, the stew is kept at the proper temperature, about 180° Fahr.—not even a simmering heat—this does not occur, the meat is tender and juicy and easy of digestion. This is easily secured by a vessel called the *Bain Marie.* It is constructed on the same principle as an ordinary glue-pot. One vessel is fitted inside an outer one. The outer one contains water, which thus surrounds the inner. The vessel is put on the fire, and the meat, vegetables, &c., in the inner vessel, the whole being covered by a lid. The water in the outer vessel comes to the boiling point, but any liquid in the inner one never reaches such a degree because of the loss of heat by evaporation. The water in the outer vessel would require to be raised above the boiling point, which cannot happen, before that in the inner could reach that point. This is the method employed by the continental peasantry, whose stews are famous for their tenderness and delicacy. "The poor peasant, with her 2 or 3 ounces of meat for a large family, puts it into a *pot au feu,* along with what vegetables she happens to have, puts it in after breakfast and leaves it there; it never gets up to boiling point; the meat and vegetables are intermingled, and a nice dinner is obtained for about one-third of what it costs our people of the same class for a lump of salt bacon." Again, the poor French peasant, says Mattieu Williams, does more with one pound of meat, in the way of stewing, than the English cook with three or four. "The little bit of meat and the large supply of vegetables are placed in a pot, and this in another vessel containing water—the *Bain Marie.* This stands on the embers of a poor little wood fire, and is left there till dinner-time, under conditions that render boiling impossible, and demand little or no further attention from the cook. Consequently the meat, when removed, has parted with its juices to the *potage,* but is not curled up by the contraction of the hardened albumen, nor reduced to stringy fibres. It is tender, eatable and enjoyable." Count Rumford says: "In many countries where soups constitute the principal part of the food of the inhabitants, the process of cooking lasts from one meal-time to another, and is performed almost without

either trouble or expense. As soon as the soup is served up, the ingredients for the next meal are put into the pot (which is never suffered to cool and does not require scouring); and this pot—which is of cast-iron or earthenware—being well closed with its thick wooden cover, is placed by the side of the fire, where its contents are kept simmering for many hours."

Vegetable food, unlike animal food, can scarcely be too thoroughly cooked, and boiling is for all the most suitable process. Starchy vegetables such as potatoes are not digestible unless they have been boiled sufficiently to cause all the starch-grains to swell and burst their cellulose envelopes. It is this that causes the potato to become mealy by cooling. Sodden and hard or waxy, they are not digestible. Potatoes should be placed in boiling water, with the addition of salt. There is no doubt that boiled potatoes in their skins retain a flavour, of which they are otherwise robbed. The skins of the potatoes do contain some small percentage of a poisonous alkaloid, solanine, which is extracted by boiling and probably destroyed. There is, therefore, some reason for the refusal to use the water in which potatoes have been boiled in their skins; but there is no reason for the throwing away of the water in which peeled potatoes have been boiled, since the alkaloid has been removed in the peelings. Steaming is, however, the most excellent method for the cooking of potatoes, no element of flavour being thereby lost.

Green vegetables require prolonged boiling to make them tender. They should be placed in boiling water, and kept boiling uninterruptedly till removed for being served. As green vegetables are specially valuable for the salts they contain, and as these salts are to a considerable extent removed by water, and specially by soft water, it is better to boil them in hard water or in water to which salt has been added, in the proportion of 2 ounces to the gallon of water.

As regards vegetables like peas, beans, and lentils, their value as food-stuffs depends to a very great extent on their being thoroughly cooked. It has been shown, for example, that when the meal of such food has been used, baked into cakes, and so cooked and eaten, 91·8 per cent of the albuminous constituent was made use of in the body; but when used in their natural form, and boiled after previous soaking in water, only 59·8 per cent was retained in the body; the rest was expelled undigested as waste. This is doubtless partly because of the meal permitting of more thorough cooking, and partly also, no doubt, because of being more readily attacked by the digestive fluids.

Loss in Cooking.—By the various methods of cooking that have been noted the meat, as might be expected, loses in weight. Obviously the loss will be greater in meat roasted or baked, because of the considerable evaporation of water and melting away of fat. The loss is least by boiling, though by this method of cooking it reaches 20 per cent, that is ⅕ of the weight, so that boiling is the most economical method of cooking. Letheby gives the following table as expressing the loss of different pieces of meat by the various processes:—

	Boiling, per cent.	Baking, per cent.	Roasting, per cent.
Beef generally,	20	29	31
Mutton generally,	20	31	35
Legs of Mutton,	20	32	33
Shoulders of Mutton,	24	32	34
Loins of Mutton,	30	33	36
Necks of Mutton,	25	32	34
Average of all,	23	31	34

The following is an example from another source:—

	In Boiling. lb. oz.	In Baking. lb. oz.	In Roasting. lb. oz.
4 lbs. of Beef lose	1 0	1 3	1 5
4 lbs. of Mutton lose	0 14	1 4	1 6

THE CONSTRUCTION OF DIETARIES.

The previous consideration that has been given to the uses of food in the body, and to the chemical composition of foods, puts us now in the position of being able to calculate with very considerable accuracy the total quantity of food required per day by persons under various conditions of life, and the proportion of the total quantity which should be contributed by the various kinds of food, albuminous, starchy, and fatty.

The principles on which that calculation is based are considered at length on p. 542, and it may be well to restate them briefly here.

1. A certain quantity of food, which must be proteid, is daily required for the repair of tear and wear of tissues, which tear and wear is practically constant, and not notably varying with work done.

2. A further quantity of food, which may be drawn principally from the starchy and fatty classes, is required, varying, however, with the work done and with the external temperature.

Now it is evident that if the tear and wear of tissue, replaceable by proteid or albuminous foods, is more or less constant, it is only necessary to keep a man under observation for some

time to learn how much that daily tear and wear amounts to, and how much nitrogenous food it is necessary to supply daily for its repair. Further, we have seen (p. 533) that even if a man remains perfectly idle, making no exertion whatever, energy is expended in the performance of the vital operations of the body, the beating of the heart, the movements of respiration, &c., and in the maintenance of the bodily temperature. This energy, we have seen (p. 532), is yielded best by the combustion within the body of starches, sugars, and fats, and may be measured by the ultimate products of their combustion which leave the body, specially carbonic acid gas. So that if a set of observations be made upon a man, remaining perfectly idle, one may ascertain not only the amount of nitrogenous food required per day to repair tissue waste, but the minimum quantity also of starches and fats that will suffice to yield energy for vital operations and bodily heat without loss to the body. That is to say, by actual experiment one may learn what is the **Minimum Diet**, consistent with the maintenance of health. If, thereafter, a second set of observations be made upon the same man, who is now set to do a moderate amount of daily work, one may ascertain what is the increased amount of fats and starches, &c., used up in the body to yield the necessary energy, and how much of such foods must be added to the diet to supply it. This set of observations will give the information needed for the determination of what is called **Standard Diet**; that is, the quantity of food daily required by the average man, doing a fair quantity of work, with the maintenance of health. Another set of observations may be made on a man, doing hard work daily, and a dietary may be thereafter constructed to suit his still increased expenditure of energy, and this may be called the **Diet for Hard Work.** Within comparatively recent years a large number of such observations have been made, specially in the Munich Physiological Institute, to which a reference has already been made (p. 540), and a high degree of scientific accuracy has thus been obtained. Previous to such observations the facts which afforded a basis for the construction of dietaries were obtained from observing the quantities of food usually taken by persons under varying circumstances. Thus Dr. Edward Smith calculated the average quantities taken by adult men and women. Dr. Playfair took the average daily food of needlewomen in London, and the average diet of the operatives during the cotton famine in Lancashire in 1862, and considered this to be the barest possible diet. It has been called **Bare-subsistence Diet, Starvation Diet** or **Famine Diet.** Then he took the mean of the dietaries of English, French, Prussian, and Russian soldiers, &c., as representing the diet of active labourers, and so on. In these calculations the large number of cases from which the average was taken got rid of any errors due to individual excess or deficiency in eating.

Bare-subsistence Diet.—Now we have seen (p. 539) that proteid food may be expressed by the amount of nitrogen it contains, and that the amount of proteid consumed in the body may be ascertained by the amount of urea given off in the urine or by the amount of nitrogen that urea contains. Further, fats and starches may be estimated by the amount of carbon given off from the body; only we must not forget that proteid foods yield carbon also. In short, we may express the quantity of food eaten, or of material used up in the body, simply in grains of nitrogen and carbon, as well as in grains of proteids, fats, and starches.

These things must be remembered in endeavouring to understand the following tables. In an experiment in the Munich laboratory, the subject of it, a watchmaker, did no muscular work, received no food, and lost from his body the following:—

Grains of Nitrogen.	Grains of Carbon.
175·2	3202·8

which represented the amount of flesh and fat of his own body consumed as tear and wear of its machinery, and to yield energy and heat for vital processes.

Now Dr. Playfair's bare-subsistence diet of needlewomen and operatives during famine is as follows:—

Nitrogenous or proteid matter,	2·33 ounces	All calculated as free of water.
Fat,	0·84 ,,	
Carbo-hydrates (Sugars and Starches),	11·69 ,,	
Total,	14·86 ,,	

If we express this in grains of nitrogen and carbon it amounts to—

Grains of Nitrogen.	Grains of Carbon.
160·8	3103·4

So that the quantity of material, lost from the body of a starving man in 24 hours, is very nearly the same as the total quantity of food introduced per day into the body in circumstances of hardship just indicated. Exactly

34 ounces of ordinary white bread, that is, 2 lbs. 2 ounces, yield—

Grains of Nitrogen.	Grains of Carbon.
160	4085

almost exactly the nitrogen of the bare subsistence diet, though 900 grains more carbon. So that we may say this quantity of bread per day is the smallest quantity that it is possible for an adult to maintain existence upon. This amount, however, it is plain, is not satisfactory as a calculating basis for ordinary circumstances, for the body loss of a starving man is not a fair gauge of what the body requires even in circumstances of no work to do, nor is the bare-existence diet of a famine-stricken population. Professor Ranke made an experiment upon himself at Munich with the intention of finding what diet was just sufficient for his bodily wants, when he did no work—with what diet, that is to say, his body would hold its own, neither gaining nor losing. The amount is as follows:—

Nitrogenous or proteid, ...	3·5 ounces	All water-free.
Fats, ...	3·5 ,,	
Carbo-hydrates (Sugars and Starches), ...	8·5 ,,	
Total,	14·5 ,,	

This total, it is to be observed, is less than that of the bare-subsistence diet; but then it is less because of the diminished quantity of carbohydrate, while it is richer in proteids, and much richer in fats, fat being worth twice its weight of carbo-hydrate in richness of carbon. Expressed in nitrogen and carbon this diet equals

Grains of Nitrogen.	Grains of Carbon.
241	3675

Dr. Edward Smith calculated the diets for the average men and women doing no work, and made it as follows:—

	Grains of Nitrogen.	Grains of Carbon.
Adult Man, ...	200	4300
Adult Woman, ...	180	3900

Dr. Letheby gives the following for the adult man (1) during idleness, (2) during ordinary work, (3) during hard work:—

Diet should contain	Grains of Nitrogen.	Grains of Carbon.
For idleness, ...	180	3816
For ordinary work, ...	307	5688
For hard work, ...	391	6823

A very large number of statistics have been collected with the object of determining what is a fair diet for the ordinary working-man, and the above are some samples of the means taken to arrive at a decision.

Standard or Model Diet.—The diet generally accepted as a fair representation not only of the total elements which a diet should contain, but also of the proportion of the various food-stuffs of which they should consist, is that of Professor Moleschott, and is given in the following table:—

Alimentary substances in a dry state required daily for the support of an ordinary working-man of average height and weight.

Nitrogenous or proteid, ...	4·587	ounces avoirdupois.
Fatty matter, ...	2·964	,,
Carbo-hydrates, ...	14·250	,,
Salts, ...	1·058	,,
Total, ...	22·859	,,

This table, it is to be observed, gives the quantities calculated free of water. Food as we take it, however, contains varying percentages of water, as the preceding tables of analysis show. If one takes 50 as the average percentage of water, then the 22·859 ounces dry solids will be 45·718 ounces of food as ordinarily consumed. Besides that there is usually taken in one form or another, as tea, &c., at least 50 to 60 ounces of water.

This standard diet, calculated in terms of nitrogen and carbon, yields:—

Grains of Nitrogen.	Grains of Carbon.
316	4860

Putting it in round numbers, we may say that an ordinary person doing a fair day's work requires a quantity of mixed food that will yield 300 grains of nitrogen and 4800 grains of carbon.

The Calculation of the Value of a Diet.—The problem in constructing a dietary is to furnish these ingredients in the simplest, most palatable, most digestible, and probably also most economical form. It will be of interest now to show how the calculations are made, and how, given any diet whatever, one could estimate its equivalents in nitrogen and carbon. The tables of analysis, which have been given in a very complete form, enable one to determine the dry albuminous, fatty, and carbohydrate material in any given food-stuff.

Let us take four examples as illustration: lean beef, white bread, oatmeal, and potato. The problem is to determine the number of grains of nitrogen and carbon in, let us say, four ounces of each of these substances.

1. **Determine what amount of dry nitrogenous (proteid) material, of dry fatty material, and of dry carbo-hydrate (starch and sugar) each contains.**

Lean Beef.—100 ounces of lean beef contain, according to table, p. 543:—

Nitrogenous,	19·3 oz.
Fat,	3·6 ,,
Carbo-hydrate,	none.

If 100 ounces of lean beef yield 19·3 ounces dry nitrogenous matter, how much will 4 ounces yield?—

$100 : 4 :: 19{\cdot}3 : x.$

Multiply 19·3 by 4 and divide by 100.

The answer is ·776 of an ounce.

In the same way, multiplying the quantity of fat in 100 ounces, namely, 3·6, by 4, and dividing by 100, gives the amount of fat in 4 ounces.

Thus

4 ounces Lean Beef contain—

Nitrogenous,	·776 oz.
Fat,	·144 ,,

White Bread.—100 ounces of white bread, according to table (p. 562), contain of—

Nitrogenous,	6·82 oz.
Fat,	·77 ,,
Carbo-hydrate,	52·34 ,,

Proceeding as before,

The quantity of nitrogenous material in 4 oz. is obtained by multiplying 6·82 by 4 and dividing by 100,

of fat by multiplying ·77 by 4 and dividing by 100,

and of carbo-hydrate by multiplying 52·37 by 4 and dividing by 100.

Thus

4 ounces of White Bread contain—

Nitrogenous,	·2728 oz.
Fat,	·0308 ,,
Carbo-hydrate,	2·0936 ,,

Oatmeal.—100 ounces of oatmeal, according to table (p. 563), contain—

Nitrogenous,	16·1 oz.
Fat,	10·1 ,,
Carbo-hydrate,	63·0 ,,

Proceeding as before, we find that

4 ounces of Oatmeal will contain—

Nitrogenous,	·644 oz.
Fat,	·404 ,,
Carbo-hydrate,	2·520 ,,

Potatoes.—100 ounces of potatoes, according to table (p. 569), contain—

Nitrogenous,	2·3 oz.
Fat,	0·3 ,,
Carbo-hydrate,	19·7 ,,

Proceeding again as before, we find that

4 ounces of Potatoes contain—

Nitrogenous,	·092 oz.
Fat,	·012 ,,
Carbo-hydrate,	·788 ,,

These results we may tabulate for ease of future reference thus:—

Amount of Dry Alimentary Substance contained in 4 oz. of Lean Beef, White Bread, Oatmeal, and Potato.

	Lean Beef.	White Bread.	Oatmeal.	Potato.
	ounce.	ounces.	ounces.	ounce.
Nitrogenous,	·776	·2728	·644	·092
Fat,	·144	·0308	·404	·012
Carbo-hydrate,	—	2·0936	2·520	·788
Totals,	·920	2·3972	3·568	·892

2. The next part of the problem is to determine what quantities of nitrogen and carbon these quantities of nitrogenous, fat, and carbo-hydrate material contain.

This we are able to do by a table of Dr. Parkes' in which is stated in grains the quantity of nitrogen and carbon in each ounce of these different classes of foods as follows:—

	Grains of Nitrogen.	Grains of Carbon.
1 ounce of Dry Nitrogenous or Proteid material contains,	69	233
1 ounce of Dry Fatty material contains,	0	345·6
1 ounce of Dry Carbo-hydrate[1] material contains,	0	194·2

To find the grains of nitrogen and carbon, therefore, in 4 ounces lean beef, (*a*) we multiply the number of grains of nitrogen (69) in 1 ounce dry nitrogenous material by ·776, the amount of dry nitrogenous material in 4 ounces of beef, and (*b*) obtain the carbon in the same quantity of nitrogenous material by multiplying by 233, adding to that the carbon contained in the ·144 oz. dry fat, thus:—

	Grains of Nitrogen.	Grains of Carbon.
4 ounces Lean Beef contain in ·776 of an ounce Dry Nitrogenous material:		
·776 multiplied by 69	53·544	
·776 multiplied by 233		180·808
4 ounces Lean Beef contain in ·144 of an ounce Dry Fat:		
·144 multiplied by 345·6,		49·7664
Totals,	53·544	230·5744

Working out the figures for the other substances in the same way, we get results ex-

[1] This does not include lactose, the form of carbo-hydrate in milk, which contains only 175 grains of carbon to each ounce.

pressed in round numbers in the following table:—

Grains of Nitrogen and Carbon contained in 4 ounces each of Lean Beef, White Bread, Oatmeal, and Potato.

	Grains of Nitrogen.		Grains of Carbon.
Lean Beef,	53½	......	230½
White Bread,	19	......	481
Oatmeal,	45	......	779
Potato,	6½	......	178½

These four illustrations have been given to show the method of calculation; and it is evident that, from the numerous tables of analysis given in preceding pages, it would be possible for any one, who knows the multiplication table, to work out the grains of nitrogen and carbon in any ordinary diet.

Thus, let us suppose a person took for breakfast the following:—

4 ounces of Oatmeal made into porridge.
10 ,, Sweet Milk.
1 pint of Cocoa (2 breakfast-cupfuls).
¼ lb. White Bread (two thick slices).
½ oz. Butter (enough for the bread).

We can determine how much of the needed daily supply of nutriment he has been provided with. The method of calculation has already been described.

	Nitrogenous.	Fat.	Carbo-hydrate.
	oz.	oz.	oz.
4 ounces Oatmeal yield,	·644	·404	2·52
10 ,, Milk, ,,	·464	·35	·428 (lactose).
1 pint Cocoa, ,,	·03	·092	·025
¼ lb. (4 oz.) Bread, ,,	·2728	·03	2·093
½ oz. (·5) Butter, ,,	·0115	·4215	—
Totals,[1]....	1·4223	1·2975	4·638 and ·428 lactose.

The calculation shows that the diet yields

Grains of Nitrogen.	Grains of Carbon.
100	1757

Suppose the same man lunches on

½ lb. (8 oz.) Mutton Chop,
1½ lb. Potatoes,

and let us suppose there are only 6 ounces edible material in the mutton, the rest being bone. This will yield, calculating in the same way,

Grains of Nitrogen.	Grains of Carbon.
104	1550

which, added to the breakfast, make 204 of the necessary 300 of nitrogen and 3307 of the necessary 4800 grains of carbon. It will be an excellent exercise for any one who has followed these explanations to construct other one or two meals, just sufficient to yield the 96 grains nitrogen and 1493 grains of carbon still wanting to complete a standard diet for a man doing a good day's work.

Proportion of Nitrogen to Carbon in Standard Diet.—To return to the standard diet, we have found that, for the repair of tissue and for the liberation of energy for work and maintenance of heat, it ought to contain 300 grains nitrogen and 4800 grains of carbon. These figures are exactly equal to a proportion of 1 of nitrogen for every 16 of carbon. Now there is no food-stuff which contains exactly this proportion of these two elements, and the most of food-stuffs are very far from it, the animal foods containing the nitrogen in excess, and the vegetable foods, as a rule, containing the carbon in excess. Thus the proportion is as follows:—

In Lean Beef	1 of Nitrogen to			4⅓ Carbon.	
,, Cow's Milk	1	,,	,,	9½	,,
,, **Human Milk**	**1**	,,	,,	**13⅓**	,,
,, **Oatmeal**	**1**	,,	,,	**17⅓**	,,
,, White Bread	1	,,	,,	25⅓	,,
,, Potato	1	,,	,,	27½	,,

Cow's milk contains evidently too much nitrogen to afford an entirely suitable diet for the adult. Human milk is nearly the proportion, but then we must remember that human milk is the diet for development and growth of tissue, and therefore contains a larger proportion of nitrogen than is needed by the full-grown person. Oatmeal comes nearest, containing rather an excess of carbon. It is evident, then, that the due proportion can only be obtained by an appropriate mixing of food, and that it is not possible to obtain it from one food-stuff alone. Thus Moleschott calculated that to obtain the necessary quantity of nitrogenous food for his standard diet *from one source only*, a person would require to eat of—

Cheese fully	12·4 oz.	Wheat Bread	46·3 oz.
Lentils	15·75 ,,	Rice	82·1 ,,
Peas	18·66 ,,	Rye Bread	92·2 ,,
Beef fully	19·7 ,,	Potatoes	320·8 (20 lbs.)
Eggs ,,	31·0 ,,		

And to obtain the non-nitrogenous material (fat, starches, and sugars), the person would require to consume of—

Rice	18·3 oz.	Rye Bread	30·0 oz.
Wheat Bread	20·0 ,,	Cheese	64·5 ,,
Peas	26·0 ,,	Potatoes	65·5 ,,
Lentils	26·2 ,,	Beef	72·5 (4½ lbs.)
Eggs	29·0 ,,		

[1] Now multiply 1·4213 by 69, and one gets the grains of Nitrogen in the diet.

Then multiply 1·4213 by 233, 1·2975 by 345·6, 4·638 by 194·2, and ·428 by 175; add the results together, and one obtains the grains of Carbon in the breakfast.

The result is, in round numbers,

Grains of Nitrogen.	Grains of Carbon.
100	1757

Thus while $1\frac{1}{2}$ pounds of beef yield the necessary 300 grains of nitrogen, it requires $4\frac{1}{2}$ to give the necessary amount of carbon; so that, to get the necessary amount of carbon from beef, three times the needful quantity of nitrogen is introduced into the body, involving labour in the expulsion of the excess, and probably also working mischief. In the same way if only sufficient rice be eaten to yield sufficient carbon, there is a great deficiency in the supplied nitrogen, and tissue waste is not repaired; while if enough is eaten to yield nitrogen, a great deal excessive carbon is introduced, leading to its being stored up as fat or in some other form.

Instead of expressing the proportion as 1 of nitrogen to 16 of carbon we may express it more simply, though not so accurately, in terms of nitrogenous and non-nitrogenous food-stuffs. When so expressed, we say that a suitable diet for an adult man should contain 1 part nitrogenous food for every $3\frac{1}{2}$ to $4\frac{1}{2}$ parts non-nitrogenous; and this affords one an easier and more rapid way of forming a conclusion as to the suitability of any particular diet. The proportion of nitrogenous to non-nitrogenous constituents of some of the more common foods is as follows:—

	Nitrogenous.	Non-nitrogenous, reckoned as Starch.
Veal,	10	1
Hare's Flesh,	10	2
Beef,	10	17
Lentils,	10	21
Beans,	10	22
Peas,	10	23
Fat Mutton,	10	27
Fat Pork,	10	30
Cow's Milk,	10	30
Human Milk,	**10**	**37**
Wheaten Flour,	**10**	**46**
Oatmeal,	**10**	**50**
Rye Meal,	10	57
Barley Meal,	10	57
White Potatoes,	10	86
Blue Potatoes,	10	115
Rice,	10	123
Buckwheat Meal,	10	130

The only foods that come near to the proportion are human milk, wheaten flour, and oatmeal, the first being deficient in carbonaceous substance and the last in nitrogenous; but the human milk is on this account all the more suited for the growing child, while for an outdoor life, marked by labour and exertion, oatmeal shows itself a well-adapted diet.

Times of Eating.—How is the amount of nourishment shown to be necessary to be introduced into the body? in how many meals? at what times of the day? are questions rather to be answered by each individual, as he finds suitable to his comfort and his business, than to be determined by a code. Certain general rules, however, can be stated with considerable definiteness.

I. The only course consistent with man's business is to introduce the food in several meals, separated from one another by intervals appropriate to the amount taken at each meal, and its nature. There are not very many persons who can devote themselves to any occupation, requiring concentration of thought or energy, soon after a very hearty meal, and it is not desirable that they should. For if a very full meal has been taken, the digestive organs find themselves taxed to their utmost, the circulation becomes exceedingly active through the abdominal organs, meaning a diminished circulation through the nervous system and other parts of the body. This is the explanation of drowsiness after a full meal. Accordingly the diet for the day is distributed in several meals, none of which ought unduly to tax the digestion.

II. The meal-times once arranged should be regularly observed. A habit is very soon established not only with the person himself, but with his digestive organs, which, as the appropriate hour returns, will be prepared, as it were, with the due supply of digestive fluid to meet the expected meal. There is nothing which so disorganizes the paraphernalia of digestion as irregularity, and nothing which is more certain, sooner or later, to establish inveterate dyspepsia.

III. The interval between each recurring meal should be sufficient to permit of a suitable period of rest for recuperation of the digestive energies. What that interval should be may be estimated from reference to p. 601, where the times of digestion of different foods are stated. One may take it that $3\frac{1}{2}$ to 4 hours, on an average, are required for the digestion of an ordinary meal, and, if so, something like an interval of at least five hours should elapse between each meal. Thus if breakfast is taken at 8 A.M., the next meal would not be before 1 P.M.; or if breakfast were at 9 A.M., the next would be at 2 P.M., and the third at 7 P.M., and so on. One must beware of the argument that a shorter interval and more frequent meals may be allowed, if a smaller quantity be taken at each meal. Dr. Beaumont's experiments and observations support the view that, *in a healthy state of body*, a moderately-sized meal is as easily and quickly digested as a small meal. So small

a piece of boiled mutton as a quarter of an ounce will require three hours to digest in the stomach, while half a pound, if properly broken down into small portions by the teeth, will be digested in the same time. It is a chemical operation that is being performed, which, within limits, is not affected in time by the quantity to be operated on. It does appear that a moderate meal and a fair interval between each is more suited to man's internal organization in health than small quantities frequently repeated. The latter is, however, in some cases of ill-health, sickness, &c., the most powerful means of treatment.

The common distribution of meals into three principal meals is the one which seems most suitable, whether these meals be breakfast (8–9 A.M.), dinner (1–2 P.M.), tea (6–7 P.M.), or breakfast, lunch, and late dinner. Many, business men in particular, allow themselves really only two good meals a day, breakfast (8–9 A.M.) and dinner (about 7 P.M.). They snatch a bite early in the afternoon, very often a cup of tea or coffee and a biscuit, or such like, sufficient to stave off feelings of emptiness, but not sufficient to yield any amount of nutriment worth calculating. They find it suits their business; and that if they take anything like a fair meal at that time they are not so active, so quick-witted, or so inclined to business as they wish. That may be so, and yet the fact remains that they supply no fresh fuel for the body just at the time when its energies are being expended with greatest rapidity. It is possible to effect a compromise, and while not taking enough to produce feelings of disinclination for work, yet to take sufficient to yield a fair supply of nutriment to the body—such as a basin of soup with bread, a chop or cutlet and potato, a dish of mince-meat and rice, or mince-meat and potato, and so on.

Breakfast at 9 A.M., dinner between 1 and 2 P.M., and tea about 6, is a very common arrangement with the working-classes of this country. If the tea is a fairly-substantial meal, it is a satisfactory enough arrangement. But it very often happens that the tea, consisting of plain bread and butter and tea, is not a very nutritious diet, and then what really happens is that there is no very substantial meal between the dinner of one day and the breakfast of the next. Under such circumstances a light meal one or one and a half hours before bed-time, say of oatmeal porridge and milk, or pease porridge and milk, or bread and milk, would be a most valuable and useful addition. The writer has known business men breakfasting early, dining at 1, taking tea at 5 in the afternoon, and nothing thereafter beyond a biscuit, with some whisky and water. It was not surprising that, under such circumstances, sleeplessness was a common complaint. With such a distribution of meals, a light supper such as has been indicated ought to be taken. Those who dine late require, of course, no further food before bed-time.

The afternoon tea, so popular with the middle and upper classes, taken between early lunch and late dinner is, under ordinary circumstances, not to be objected to, if the tea be freshly made and not too strong. The individual with inclinations towards indigestion had, however, better take care, lest it suddenly arrests the digestion of his lunch, not yet completed, and brings him to dinner with a stomach most unwilling to receive as yet any further supplies.

It may be remarked in concluding these considerations that the resistance of the body to disease, particularly to infection, is least after a long fast. It is, therefore, undesirable to engage in the day's work unfortified by food, specially if one's business brings one within the reach of any unhealthy influence. "It is well known," says Dr. Combe, "that the system is more susceptible of infection, and of the influence of cold, miasma, and other morbid causes, in the morning before eating than at any other time; and hence it has become a point of duty with all naval and military commanders, especially in bad climates, always to give their men breakfast before exposing them to morning dews and other noxious influences. Sir George Ballingall even mentions a regiment quartered at Newcastle, in which typhus fever was very prevalent, and in which, of all the means used to check its progress, nothing proved so successful as an early breakfast of warm coffee. In aguish countries, also, experience has shown that the proportion of sick among those who are exposed to the open air before getting anything to eat, is infinitely greater than among those who have been fortified by a comfortable breakfast." "In some constitutions," says Pereira, "especially those denominated delicate, much exercise, either of body or mind, before breakfast, operates injuriously, producing exhaustion, languor, and unfitness for the ordinary occupations of the day. These facts show the importance of breakfasting soon after rising and dressing, at least in many cases. I am fully aware that there are numerous exceptions to this. Some persons not only suffer no injury from, but actually appear to be benefited

by, active exercise taken before breakfast, its effect being with them to create or augment the appetite. But in others the effects are those which I have already stated. I am satisfied, from repeated observation, that in children disposed to spasmodic and other brain diseases, the practice of making them attend school for two hours before breakfast is injurious; and I fully agree, therefore, with Dr. Combe, that in boarding-schools for the young and growing, who require plenty of sustenance, and are often obliged to rise early, an early breakfast is an almost indispensable condition of health. Epileptics, and especially those disposed to morning attacks, should invariably breakfast soon after rising. I think I have seen the fits brought on by neglecting this precaution. For travellers a light breakfast before starting is a great protection against colds and subsequent fatigue or exhaustion."

These general rules are all that one can lay down with any pretension to wide application. Within them individuals must consult their own tastes, business habits, and it may be also personal peculiarities. Nevertheless, any one who passes much outside of such general regulations will probably find, in time, that he has erred and incurred the punishment of digestive evils, which once induced are not very easily exorcised.

Variations in Diet according to Age, Sex, Work, or Exercise.—To consider the effect of work and exercise first. We have already had abundant occasion for observing that the broad principle on which diet should be varied with work is, that energy for work is liberated most easily and economically from fats and sugars and starches. So when there is increased work or exercise, calling for more food, the increase should take the form mainly of additions of these to the diet, and not so much of meaty constituents. As a matter of practical experience it is found that some increase in the nitrogenous foods is also demanded, not because of increased tissue waste, but because an increased supply of digestive fluids in the alimentary canal is needed for the digestion of the added supply of food, and these cannot be manufactured in the body without an increase in the quantity of nitrogenous food. Further, it is found that the consumption of foods of the animal kind stimulate the combustion within the body of fatty and starchy materials, and thus the energy is more rapidly liberated from the latter kinds of food when an increased supply of animal, or, to speak more correctly, nitrogenous food is taken with them. Nevertheless it is true that the added labour is to be accomplished at the expense principally of fatty and starchy food.

As regards age: the standard diet applies to the prime of life. Modifications are requisite for the extremes of youth and old age. The relative quantities required for different ages are shown in the following table, which represent the smallest amount of food, according to the investigations of the Munich physiologists, necessary for different ages:—

	Nitrogenous.	Fat.	Carbo-hydrate.
Child under $1\frac{1}{2}$ years, ...	$\frac{3}{4}$ to $1\frac{1}{4}$	1 to $1\frac{1}{2}$ fully	$2\frac{1}{10}$ to $3\frac{1}{10}$.
Child from 6 to 15 years, ...	$2\frac{4}{10}$ to $2\frac{8}{10}$	$1\frac{1}{3}$ to $1\frac{3}{4}$	$8\frac{8}{10}$ to $14\frac{1}{10}$.
Man (moderate work), ...	$4\frac{1}{10}$	2	$17\frac{6}{10}$.
Woman, ...	$3\frac{1}{4}$	$1\frac{1}{2}$	$14\frac{1}{10}$.
Old Man, ...	$3\frac{1}{2}$	$2\frac{4}{10}$	$12\frac{3}{10}$.
Old Woman,......	$2\frac{8}{10}$	$1\frac{3}{4}$	$9\frac{1}{10}$.

The figures denote ounces and fractions of ounces, and the quantity does not include water, but represents the dry nitrogenous, &c., material. By doubling the figures one will obtain the quantities, as applicable to food in the ordinary state in which one consumes them.

As regards the food of children, the really essential thing to remember is that they require a larger proportion of nitrogenous food than the adult, to meet the demand for material with which to build up bone, muscle, &c. Human milk supplies that demand, containing, as we have several times noted, a larger proportion of nitrogen as compared with carbon than is suitable for the adult. On the other hand, these facts are so little known that the prevailing practice is, as soon as a child ceases to be fed with milk, to supply it with food of all others deficient in the very element in which it should abound—corn-flour, tapioca, arrow-root, semolina. These, as we have observed (p. 542), are practically entirely devoid of nitrogen, are almost exclusively starchy in character, and starch is just the class of food-stuff which the child's digestive apparatus is least fitted to deal with. There is no starch in milk, though there is sugar. Such foods are only made tolerable for a child by the milk with which, in part, they are usually made and administered. Well, then, a child's diet ought to be rich in nitrogenous food-stuffs. Here again is oatmeal eminently serviceable, made into well-cooked porridge, with additions of soup, broth, egg, &c., as mentioned in detail on p. 450. With children more frequent meals with shorter intervals are required, prolonged fasting being badly borne. In determining whether a child is receiving a

sufficient diet, one must not lay too much stress upon gain in weight alone. Weight may be gained through deposition of fat, owing to a diet excessively rich in starch, sugar, or fat, while all the time the child is suffering from nitrogen starvation. It is not uncommon to see a big, fat child, which would be called a picture of health but for its pasty complexion, but with bones so soft that they yield to its own weight. Such is the result of a diet too rich in starch, and wanting in nitrogenous food. Therefore, in estimating the health and healthy growth of a child, one must take into account not only weight, but firmness of flesh, redness of lip and cheek, and straightness of bone. Soft flesh, yielding bones, and white face proclaim with absolute certainty improper *quality* of food, no matter what may be the *quantity* the child is consuming. The food of children ought to be given in a more dilute condition than that of adults. They are more likely "to have too little water in their food than too much." "Hardly ever is there a mother or a nurse who imagines that a child can be thirsty without being hungry at the same time. Much discomfort and a good deal of sickness is a result of the fact that infants must eat in order *not* to be thirsty, and have frequently to go thirsty because an over-exerted and disordered stomach will not accept any more food." There is undoubtedly a necessity of mothers now and then giving some water to their children.

The following examples of children's dietaries may be useful:—

St. Thomas's Hospital, London.

(Intended for all Children under 10 years of Age.)

MIXED DIET:—12 oz. Bread; ¾ oz. Butter; ½ pint Milk for Breakfast, the same for Tea; 2 oz. Mutton, when dressed, roast, or boiled alternately; ¼ lb. Potatoes or fresh Vegetables; 6 oz. of Rice or Bread Pudding; ½ pint of Milk.

MILK DIET:—Daily—1½ pints of Milk; 8 oz. Bread; ½ oz. Butter; 6 oz. Rice or Bread Pudding.

Birmingham General Infirmary.

FULL DIET:—Breakfast—1 pint of Milk.
Dinner— 2 oz. Cooked Meat, 6 oz. Potatoes, and 6 oz. Bread.
Supper— ½ pint of Broth or Gruel.

Glasgow Sick Children's Hospital.

	1st (Milk Diet).	2d.	3d (Full Diet).
BREAKFAST, 8 a.m.	Bread and Butter.* Bread and Milk.	Porridge, ½ pint. Bread and Butter.*	Porridge, ½ pint. Bread and Butter.*
DINNER, 12 noon.	Milk Pudding. Extras as ordered.	Broth, ½ pint. Bread. Milk Pudding.	Minced Collops of Beef or Mutton, 2½ oz. cooked, or Stewed Rabbit. Mashed Potatoes, 3 oz. Milk Pudding.
TEA, 4 p.m.	Milk. Bread with Butter.*	Cocoa, ½ pint. Bread with Butter,* Dripping, or Treacle.	Cocoa, ½ pint. Bread with Butter,* Dripping, or Treacle.
	At 5 a.m. and 7 p.m., Milk with "a piece." Total quantity of Milk per day, 1 pint.	Total Milk per day, 1 pint.	Total Milk per day, 1 pint.

* Butter ¾ oz. daily, and Bread as much as is desired.

BROTH.—Alternately Hough and Neck of Mutton, ½ lb. to pint.

PUDDINGS.—Rice, Sago, Tapioca, Bread and Butter with Eggs, all made with Milk and Sugar—Milk ½ pint per Child.

EXTRAS.—Custard (1 Egg to ½ pint Milk), Chicken Soup, Chicken, Eggs, Chops, Fish, Meat-extract, Raw-meat, Beef-juice, Beef-tea (1 lb. to the pint, or stronger if ordered), Jellies, Isinglass, Corn-flour, Arrow-root, Stimulants, Barley-water and Aerated-waters, Cabbage, Turnips.

DINNER.—In order to secure variety, all on Broth and Meat Diet will have a Fish Dinner on Wednesday. On other days the Meat Dinner will go the round of the articles mentioned; and the Sisters will exercise their judgment to suit varying appetites by interchange and sharing of diets, so far as consistent with Medical restrictions.

School Boys about 10 years of age should receive about ½ the nitrogenous food required by active men, and about ¾ths the quantity of carbonaceous food.

Diet for the aged, it has been urged, should, in its kind, approach more nearly to that of childhood. As a rule there is less activity in all the bodily processes, slower heart-beat, slower respiration, and diminished combustion changes going on. All this implies less consumption of material, and is usually accompanied by diminished appetite, weaker digestion, and increased sensitiveness to cold. This implies as a whole less food, and the proportion between the diet of the active man and that of the old man is shown in the table on p. 617. The kind of food given should also be such as will suit the enfeebled digestive powers. Milk may,

with advantage, bulk largely in it, fish, eggs, butcher-meat also, but in diminished amount, milk puddings and so on. Whatever be the opinion as to the use of stimulants by the healthy among young men and women, and men and women in their prime, there is no doubt that the aged feel the benefit of some small amount of stimulant, adding as it does to their relish for food, and aiding its more rapid digestion. An old person cannot with impunity indulge in a full and rich diet, unless he is leading as active and vigorous a life as the man in his prime. The favourite example of how a healthy old age can be attained on a very simple diet is that of Cornara, "a Venetian of noble descent, who lived in the 15th and 16th centuries, and attained an age of upward of 100 years. Impressed with the conviction that the older a man gets and the less amount of power he possesses the less should be the amount of food consumed, in opposition to the common notion that more should be taken to compensate for his failing power; he, at about 40 years of age, resolved to enter upon a new course, and betake himself to a spare diet and scrupulously regular mode of life, after having, as he says, previously led a life of indulgence in eating and drinking, and having been endowed with a feeble constitution and "fallen into divers kinds of disorders, such as pains in my stomach, and often stitches, and spices of the gout, attended by what was still worse, an almost continual slow fever, a stomach generally out of order, and a perpetual thirst." He also did all that lay in his power, "to avoid those evils which we do not find it so easy to remove. These are melancholy, hatred, and other violent passions, which appear to have the greatest influence over our bodies. The consequence was," he goes on, "that in a few days I began to perceive that such a course agreed with me very well; and by pursuing it, in less than a year I found myself (some persons, perhaps, will not believe it) entirely freed from all my complaints . . . I chose wine suited to my stomach, drinking of it but the quantity I knew I could digest. I did the same by my meat, as well in regard to quantity as to quality, accustoming myself to contrive matters so as never to cloy my stomach with eating and drinking; but constantly rise from the table with a disposition to eat and drink still more. In this I conformed to the proverb which says that a man, to consult his health, must check his appetite. . . . What with bread, meat, the yolk of an egg, and soup, I ate as much as weighed in all 12 ounces, neither more nor less. . . . . I drank but 14 ounces of wine." He remained in possession of all his faculties to the close of his life, and wrote his treatises between his eighty-third and ninety-fifth years.

As regards Sex: women require less food than men, when engaged in indoor work—a tenth less, it has been estimated. "Ladies in luxurious repose consume about the same amount as young school-boys." If women are engaged in active outdoor work, as in farm service, their diet approaches more nearly that required for active men.

The Regulation of Diet according to Season or Climate.—The differences in our household arrangements, as regards heating, between winter and summer afford a rough, but very accurate notion of the differences within the body, according to the degree of coldness of the external atmosphere. In cold weather we burn more coals or other fuel to keep up a moderate temperature in the house, and in the body an increased combustion of the heat-yielding substances goes on to maintain the regular temperature of the body. These substances are specially carbo-hydrates and fats, but more particularly the latter. To supply the material for this increased combustion more food is necessary, and particularly more fatty and starchy food. Thus our food should vary in nature and amount with the change of seasons in our temperate climates, just as our consumption of coal varies, or just as the nature of our clothing varies. In persistently cold regions of the earth, in the arctic regions, for example, the inhabitants regularly consume a much larger daily supply of food than anything we are accustomed to; and fatty substances form a very large proportion of the diet. The air in these regions is condensed because of the cold, and a given volume of air will contain a much larger quantity of oxygen than the same volume in a temperate climate, and still more than the same volume in a hot climate. Fats contain a considerably larger proportion of carbon than sugars or starches, and thus the larger quantity of oxygen in the air and the greater proportion of carbon in the fat form the complement of one another, the supporter of combustion and the combustible substance. These facts account for the large quantity of food eaten by the inhabitants of cold regions. It is a matter of common observation in cold climates, or in a very cold season of a temperate climate, that the badly-fed labourer does bad work, and is among the first to succumb to cold. According to Sir John Ross, an Esquimaux will

eat perhaps "twenty pounds of flesh and oil daily," and the children of the arctic regions find fatty substances more toothsome morsels than sweetmeats. According to Sir Anthony Carlisle, "in one of those late extravagant voyages to discover a north-west passage, the most northern races of mankind were found to be unacquainted with the taste of sweets, and their infants made very wry faces, and sputtered out sugar with disgust; but the little urchins grinned with ecstasy at the sight of a bit of whale's blubber." But such an explanation hardly covers the enormous gastronomic feats related by travellers, such as Sir George Simpson's two men of the Yakuti, who in less than two hours and a half consumed each 36 avoirdupois pounds of beef and 18 lbs. of butter. The fact that, after such a feast, the men remain in a state of stupor for three or four days, without further food or drink, and are meanwhile rolled about to promote digestion, shows how abnormal is the diet and how unjustified by the extreme and enduring cold. Great eaters have also been found in climates which made no demand for extraordinary diet—among the Hottentots and Bosjesmans, for example. The point to note is, nevertheless, that a cold external temperature demands a larger than usual supply of food, and that fatty food should bulk largely in the added quantity, the internal combustion of the fat doing far more for the maintenance of bodily warmth than extra clothing.

In warm climates the conditions are reversed, the external temperature may be at certain times above the bodily temperature. Consequently there is less need for liberation of heat within the body. A diminished supply of food is, therefore, required, and of a kind whose combustion will not yield heat in great amount. Moreover the atmosphere is rarefied, and a supply of oxygen for the combustion of highly-carbonaceous food would involve laboured respiration. Rice and sugar contain carbon in much less quantity than fat (see p. 532), 100 parts of starch requiring 120 of oxygen for complete combustion, whereas 100 of fat require 293 of oxygen. Moreover, starches contain a very considerable proportion of oxygen wherewith the combustion may be accomplished, so that starchy foods and other light vegetable diets are evidently best suited for hot climates. The fruits and vegetables preferred by Southerns yield only about 12 per cent of carbon, while the whale's blubber enjoyed by the Greenlander yields 66 to 80 per cent.

The frequency of diseases of the liver in hot seasons and tropical climates, was ascribed by Liebig to the accumulation of carbon in the system. It is, at any rate, due to the accumulation within the body of nutritive material in excess of the bodily demands, and in excess of what the bodily processes can dispose of under the climatic conditions. Thus, speaking of diet in India, Sir Joseph Fayrer says "the diet should be plain and simple. New arrivals should abstain from much animal and stimulating food, with a view to avoid plethora, dyspepsia, malassimilation, and congestion of the already over-taxed liver and eliminative organs. Curries, as generally prepared, should be sparingly consumed." He urges that the mode of living should not be rapidly changed by those arriving from a temperate climate. The habit of the digestive organs is not to be upset with impunity, and therefore the natives should not be copied in respect of diet, but the usual European diet should be gradually modified to suit the altered conditions of climate. Considering the variety of the ordinary British feeding this can be very easily done, the principles being the diminution in the total quantity of nutritive material (which can be done without diminishing the bulk of the diet by substituting articles less rich in nutriment), the substitution of vegetable diet for fatty materials, and increase in fruits. Fayrer says that, as a general rule, people eat too much in India, more than they can assimilate. As an example of a dietary he says, "a cup of chocolate, cocoa, coffee, or tea may be taken before starting for the morning ride or walk; a plain breakfast of the same, with bread and butter and eggs, or a little bit of chicken (more than the bread and butter is not often needed); luncheon or tiffin at 1 or 2 P.M., with very little animal food, a cutlet or the leg of a fowl with vegetables will suffice. . . . The evening is the best time for dinner—the principal meal of the day. It should be plain and simple, with as few dishes as possible. Nothing can be more prejudicial than a great variety and number of highly-seasoned courses. 'To leave off with an appetite' is a good maxim in temperate climates, and better still in tropical. . . . It may be generally stated that temperance both as regards food and drink is of cardinal importance." To every other hot climate besides India these precepts are equally applicable.

In temperate climates a mean between these two extremes is indicated, which is yielded best by a mixed animal and vegetable diet, and which is made to vary in quantity and in the

proportion of the fatty and starchy ingredients with the changes of the season.

It would be a very great benefit to the health of the population of Great Britain if these changes in diet required by the seasons were more recognized than they are, more particularly if the indications for the adoption of a more fatty or oily diet, with the advent of the colder months, were followed. During the cold season it is not cold simply with which we have to contend, but a raw cold, a moist cold, due to the quantity of watery vapour in the atmosphere. On the continent of Europe the cold is often much more intense, but it is more easily borne, because of the crispness and dryness of the air. The cold moist atmosphere robs the body of its heat with far greater quickness and more unequally. The garments become moist, and their power of conducting heat away from the body becomes greatly increased, so that it is a matter of great difficulty, when engaged out of doors, to maintain the bodily temperature at its uniform rate. These are just the circumstances which demand more rapid combustion of highly carbonaceous substances, such as fat, in the body. It is because it meets such a demand that the free use of cod-liver oil as a medicament is found so beneficial in our climate during the winter months, and just for the same reasons that it derives its value in warding off lung affections. Let the lean man, or the young lady who, in spite of her furs, shivers at the bare approach of "chill November," take to cod-liver oil, or to a plentiful supply of fat meats in the dietary, with the close of September, and they will both be compelled to confess that they never passed through a winter with such comfort and with less sensitiveness to the cold.

Diet for Training.—When a person goes into training for the purpose of being fitted for some great exertion of strength or of speed, there are several objects which he wishes to attain by the process. He wishes to increase the vigour of his muscles by adding both to their firmness and their actual bulk; he wishes to free his body of deposited fat; he wishes to increase the expansion of his lungs by developing his respiratory muscles, in order to "increase his wind;" he wishes to increase the strength and regularity of the contractions of the heart, so that its action will not become tumultuous under the exertion; and he wishes to unload of accumulated effete products the organs for the removal of waste, so that they shall be free actively to deal with the waste products rapidly produced under exertion. These objects are accomplished mainly by diet and exercise. Exercise, when properly arranged and graded, increases the tone and actually causes increased development of muscle—the muscles of locomotion, of respiration, and of the heart alike. It is the most rapid means of clearing out the excretory organs, and of causing the consumption of stores of fat and glycogen laid down in the body. The diet to be appropriate must fulfil certain indications. In the first instance it must never be in excess, and it must be of the most easily digested kind. Then it must supply material for the rapid increase of muscular development, and must on that account consist largely of nitrogenous material. Moreover, at the beginning of training, the diet, being mainly nitrogenous, stimulates the consumption within the body of the accumulated fats and carbo-hydrates. At the same time the diet, particularly as the training progresses, when the body has lost its fat, must not be so devoid of fat and carbo-hydrate as to cause the tissue of the body itself to be called upon for the supply of energy, as that would rapidly diminish the power of endurance. This is what "overtraining" leads to. Lean meat, therefore, enters largely into the diet, cooked by broiling or roasting, and not overdone. "Beef and mutton are the meats to be preferred, and it is not necessary that all the fat should be excluded. Stale bread or dry toast, potatoes, and some kind of green vegetables in moderation, are the appropriate articles to be taken in conjunction. Water-cresses are considered good. Pastry, flour-pudding, sweets, and made dishes, should find no place in the dietary of the man in training. The farinaceous articles, as rice, sago, &c., are allowable, but should only be taken to a moderate extent. To avoid too great sameness is an important point, especially with those who have been previously accustomed to a liberal diet; at the same time it is not desirable that the person should be tempted to eat to satiety. A full stomach, as is well known, disposes to inactivity. Condiments, as pickles, sauces, &c., are objectionable, on account of their effect being to force an appetite, which should be simply allowed to have its natural play. . . . The sensation of thirst may be taken as affording a correct guide upon the point of the amount of liquid to be consumed; but instead of drinking freely at a draught to satiety, the liquid should be sipped in small quantities, to give time for absorption, and thus satisfy thirst without incurring the risk of introducing a surplus amount into the stomach. In this way the error is not likely to be committed of drinking

too much. The liquids consumed must be of a simple and unexciting nature. Beer and the light wines are allowable, but spirits should be scrupulously avoided. Tea, coffee, and cocoa may be taken according to inclination, and, as a simple drink, nothing is better than toast and water, or barley-water. The proper number of meals to be taken during the day consists of three—viz., one about 9 A.M., the second between 1 and 2 P.M., and the third in the early part of the evening;" this is how Dr. Pavy summarizes the requirements of diet for training.

The following shows the system adopted at Cambridge in the training for the summer races:—

Rise at 7 A.M. A run of 100 or 200 yards as fast as possible.

Breakfast, at 8·30 A.M., of meat—beef or mutton—underdone; dry toast; tea—two cups, or, towards the end of training, a cup and a half only; and water-cresses occasionally.

Dinner, about 2 P.M., of meat—beef or mutton; bread; vegetables—potatoes, greens; and one pint of beer. (Some colleges have baked apples, or jellies, or rice-puddings.) For dessert, oranges, or biscuits, or figs, with two glasses of wine.

About 5·30 P.M. a row to the starting-point and back.

Supper, about 8·30 or 9 P.M., of cold meat; bread; vegetables, lettuce or water-cresses; and one pint of beer.

Retire to bed at 10 P.M.

Economy in Diet.

"Cheap and nasty" is generally regarded as a saying which is not very often inaccurate when applied to clothing, to furniture, and such like articles. That it is equally applicable to food is a belief not easily dislodged from the minds of the people. Cheap beef must necessarily be inferior beef, the less expensive portions of a carcass must be the poorer portions of it, are articles of this creed; and if there is one class of the population that looks upon the attempt to live cheaply as mean and degrading, it is the class that can least afford to spend more than is absolutely necessary upon the diet. The estimation of the value of food by its cost is wholly arbitrary, and, as we shall see, misleading. If the true method of estimating the value of food-stuffs by their capacity to nourish the body, and the means by which such an estimation could easily be made, were properly understood by the people, a complete revolution would speedily be effected in the dietaries of the poorer classes. Money that is wasted on dearer food-stuffs, under the delusion that they are the stronger and more nourishing, would be saved, if only to give variety by the extras that could be purchased with it, and perhaps to improve the condition of the thrifty in some other direction. A few examples will best show the relation between nutritive value and cost. The following table exhibits the quantity of nutritive material contained in half a pound (8 ounces) of each substance, and its cost:—

½ lb. of Oatmeal	yields of nutritive material	7·136	ounces	at a cost of	1*d.*
,, Fine Flour	,, ,, ,,	6·848	,,	,,	1*d.*
,, Bacon	,, ,, ,,	6·648	,,	,,	5*d.*
,, Pease-meal	,, ,, ,,	6·499	,,	,,	1*d.*
,, Indian Corn Meal	,, ,, ,,	6·424	,,	,,	½*d.*
,, Sago	,, ,, ,,	6·2	,,	,,	1*d.*
,, Peas (dried)	,, ,, ,,	5·995	,,	,,	1*d.*
,, Figs	,, ,, ,,	5·832	,,	,,	2*d.*
,, White Bread	,, ,, ,,	4·794	,,	,,	¾*d.*
,, Dunlop Cheese	,, ,, ,,	4·618	,,	,,	5*d.*
,, Rye Bread	,, ,, ,,	4·349	,,	,,	½*d.*
,, Fowl	,, ,, ,,	2·060	,,	,,	7*d.*
,, Egg	,, ,, ,,	2	,,	,,	4½*d.*
,, Salmon	,, ,, ,,	1·997	,,	,,	7*d.*[1]
,, Lean Beef	,, ,, ,,	1·832	,,	,,	6*d.*[1]
,, Potato	,, ,, ,,	1·784	,,	,,	¼*d.*
,, Cod	,, ,, ,,	1·72	,,	,,	2*d.*[1]
,, Milk	,, ,, ,,	·994	,,	,,	⅜*d.*
,, Buttermilk	,, ,, ,,	·698	,,	,,	⅛*d.*

[1] Allowance is made in calculating the cost for a considerable portion not edible, bones, &c.

Or we may represent the same thing by putting down the quantities of nutritive material 1*d.* will buy in the form of each of these different substances:—

		Nutritive material in ounces.		
1*d.*	will buy	12·848	as	Indian Corn Meal.
1*d.*	,,	8·698	,,	Rye Bread.
1*d.*	,,	7·136	,,	Oatmeal.
1*d.*	,,	7·136	,,	Potato.
1*d.*	,,	6·848	,,	Fine Flour.
1*d.*	,,	6·449	,,	Pease-meal.
1*d.*	,,	6·392	,,	White Bread.
1*d.*	,,	6 2	,,	Sago.
1*d.*	,,	5·995	,,	Peas (dried).
1*d.*	,,	2·916	,,	Figs (dried).
1*d.*	,,	1·864	,,	Buttermilk.
1*d.*	,,	1·329	,,	Bacon.
1*d.*	,,	1·324	,,	Milk.
1*d.*	,,	·923	,,	Cheese (Dunlop).
1*d.*	,,	·86	,,	Cod Fish.
1*d.*	,,	·445	,,	Egg.
1*d.*	,,	·305	,,	Lean Beef.
1*d.*	,,	·294	,,	Fowl.
1*d.*	,,	·285	,,	Salmon.

Taking four of these, and expressing the nutritive material in terms of nitrogen and carbon, we find that—

		Grains of Nitrogen.		Grains of Carbon.		
1*d.*	will buy	90	and	1558	as	Oatmeal.
1*d.*	,,	52	,,	1428	,,	Potato.
1*d.*	,,	50½	,,	1282	,,	White Bread.
1*d.*	,,	18	,,	77	,,	Lean Beef.

Thus one penny's-worth of oatmeal will give almost 5 times the nitrogen of one penny's-worth of lean beef and 20 times the amount of carbon, and three pennies expended on oatmeal will buy 270 grains of nitrogen and 4674 grains of carbon,—almost the very quantity required for the daily supply of a man doing active work.

In the prison of Glasgow the following diet was given to 10 prisoners (5 men and 5 boys), all under sentences of two months' imprisonment, and all employed at light work, picking hair and cotton:—

Breakfast:—8 oz. oatmeal made into porridge, with a pint of buttermilk.

Dinner:—3 lbs. of boiled potatoes, with salt.

Supper:—5 oz. of oatmeal made into porridge, with half a pint of buttermilk.

At the beginning of the dietary eight of the prisoners were in good health and two were in indifferent health; at the end all were in good health, and they had on an average gained more than 4 lbs. each in weight, only one prisoner (a man) having lost in weight. The greatest gain was 9 lbs. 4 oz., and was made by one of the men. The prisoner who was reduced in weight had lost 5 lbs. 2 oz.

This diet contains 302 grains of nitrogen and 5260 grains of carbon, more than the full quantity required per day for active work.

Its cost, including cooking, is 2¾d.[1]

As a final illustration of the fact that the dearer diet is not necessarily the most nourishing, we may give an example of two breakfasts.

We take first the breakfast given on p. 614, the nutritive material of which has been there calculated.

BREAKFAST A,

4 ounces Oatmeal, made into porridge, 10 ounces Milk, 1 pint Cocoa, ¼ lb. Bread, ½ oz. Butter,	Yields 100 grs. Nitrogen, 1757 ,, Carbon,	Costs 3*d.*

BREAKFAST B,

1 pint Coffee, 1 Egg, ¼ lb. Bacon, ½ lb. Bread, 1 oz. Butter,	Yields 79½ grs. Nitrogen, 1792 ,, Carbon,	Costs 5¾*d.*

The advantage here lies with breakfast A, its 20½ grains of nitrogen in excess of B being of more benefit than B's 35 grains excess of carbon. Yet breakfast A consists of half the quantity of bread and butter. It is plain that the egg and bacon, which add to the cost of B, do not yield the nutriment contained in the oatmeal of A. The cost of A would be still further reduced by substituting buttermilk for sweet milk. The cocoa is also counted to the advantage of A, for it contains a large quantity of nutriment, as shown in the table in next section, and, as prepared, the cocoa is all consumed, whereas coffee is used only in infusion, which contains really no nutritive properties, though it possesses markedly stimulating qualities. These illustrations are sufficient to show that a person may live cheaply and yet introduce into the body all the nutriment necessary in a highly useful and digestible form.

Effects of Excessive or Deficient Diet.

The Effects of Deficient Diet are shown in their most extreme form in cases of starvation. In such a condition the tear and wear of tissue

[1] The calculation of the nutritive equivalents is made from the table on page 563, which gives the analysis of the finest oatmeal. Probably the meal actually used would not show such a good analysis, and we may, therefore, allow that probably the diet would scarcely contain so much nutritive material as the calculation represents. Even with such an allowance it is a substantial and sufficient diet. Then the estimate of cost is low, because in a prison, where enormous quantities are bought, it is a wholesale price that is paid, and considering the number cooked for the expense of cooking would be trifling. The same materials bought by the working man or his wife could scarcely cost less than 3¾*d.*

is not replenished, and the amount of nitrogen, expelled in the urine, indicates the exact loss of organized tissue. The amount falls for two or three days after food ceases to be given, as if some surplus proteid matter, not distinctly built up into tissue, were first consumed, and thereafter the amount expelled remains at a certain minimum daily amount, which seems to bear a proportion to the body weight. The material needed to yield energy for vital operations and for the maintenance of heat is derived from the stored-up fat of the body to begin with. Thus after the first few days, when stored-up material is all consumed, the vital functions are carried on at the expense of the tissues themselves, which gradually undergo oxidation to meet the demands. If the temperature of the body be maintained by external means, death by starvation will be delayed, because less consumption of material is necessary to yield heat. It has been found that death occurs in the case of man—cases of complete abstinence from food and drink—in 8 to 10 days, but in some cases it has been observed to be delayed to from 21–24 days; but the period will, of course, depend upon the condition of the body to begin with—upon the quantity of stored-up material it may possess. When water is supplied the period is lengthened. In the case of six melancholiacs, who took water, death did not occur for 41 days. It is remarkable to observe the differing degrees to which the various organs suffer. By the time death occurs almost all fat has disappeared from the body. Next to fat the glandular organs suffer most, the spleen losing 63 per cent of its weight and the liver 56 per cent. The muscles lose 30 per cent, and the blood 17 per cent. The heart and central nervous system lose very little. Their nourishment seems to be maintained at the expense of the other tissues, their activity being so absolutely necessary to continued existence. The immediate cause of death appears to be inability longer to maintain a high enough temperature owing to the combustion of the chief heat-yielding substances. A condition of torpor, similar to that produced by cold, sets in, and leads to death. The person may be roused from this condition by the application of heat; and this is the first thing to be done, in attempted rescue from starvation, viz. to restore bodily warmth, and to supply food very slowly and gradually.

Now if a well-nourished person suffers for a few days only from deficient diet, the tissues of the body will not feel the loss, any stored-up material being sufficient to yield the deficit. If, however, the deficiency be long continued, this stored-up material will disappear sooner or later according to the daily amount of the deficiency, and, thereafter, any continued deficit will have to be made good from the tissues themselves, so that a modified and slow state of starvation will arise, weight will be steadily lost, and the characteristic results of the deficit will appear. This state of modified starvation may arise, even though the diet may appear to be abundant in quantity, and even though the person may actually gain in weight. Thus a diet may regularly contain more fats and carbo-hydrates than the person requires for energy and heat, excess being stored in the body, but the diet may, at the same time, be deficient in nitrogenous foods, so that the person is daily expelling from the body, as the result of tear and wear, more nitrogen than the diet yields, the excess of expenditure over income being drawn from the muscles, &c., while the loss in nitrogen is not in bulk so great as the gain in fat, and is, therefore, masked. A state of nitrogen starvation may thus arise while the person becomes actually fatter. This is not so uncommon among children fed on too starchy food. The evidence of this would be found in the absence of a healthy colour and in the flabbiness of the muscles and thinness of the bones felt beneath the fatty layer under the skin. As a rule, however, defective diets are so all round, and general leanness, loss of strength, languor, and general weakness betoken the true condition.

The Effects of Excessive Diet are much more common than those of defective diet. There is no doubt that many people habitually eat to excess, being urged thereto by sauces, condiments, stimulants, &c. With a plain, simple fare, a healthy appetite usually speedily indicates when the stage of satisfaction has been reached, and there is little temptation to pass beyond it. But with a great variety of food, made dishes, and culinary devices, healthy instinct is confused or disobeyed. A single excess will, of course, lead only to temporary disturbance, but continued excess leads to marked and wide-spread disturbance. Fat accumulates in the body, the liver becomes oppressed with its stores of unnecessary material, digestion becomes impaired from the excessive demand upon its operations, the attempt to dispose of the excessive material burdens the organs of excretion, and, owing to their inability to dispose of all the waste products, effete matters remain in the circulation. The blood charged with such materials is less fit to nourish the body, and

organs, not at first concerned, become thus affected indirectly, notably the brain and nervous system. Thus indigestion, sluggish and gorged liver, disordered bowels, headache, sleeplessness, plethora, giddiness and irritability are among the earlier results. Gouty and other allied conditions may arise. The evils from excess in animal food are more marked than from excess in vegetable food. Deposition of fat, disordered liver, and so forth, readily arise in the latter, but the retention within the system of the products of nitrogenous excess, introduced to greatest extent in animal food, are more particularly injurious. Whenever, with excess of food, there is deficient exercise, the evils are greatly magnified, and it is under such circumstances that the evils of excessive animal food appear in full force.

Diets suitable for Special Bodily Conditions.

Corpulence, and Banting's System.—William Banting was a London tradesman who, at sixty-six years of age (Aug. 1862), with a height of 5 feet 5 inches, weighed 14 stones 6 lbs. In spite of a most active life, without self-indulgence of any kind, he suffered from what he calls the "lamentable malady" of ever-increasing stoutness. He was compelled to go down-stairs slowly backwards to save the pain of the weight on his ankle and knee joints, and the slightest exertion made him puff and blow. He complains pathetically of the pain inflicted on him in the street or in public assemblies by the remarks of the "cruel and the injudicious." He had "tried sea-air and bathing in various localities, with much walking exercise; taken gallons of physic and liquor potassæ advisedly and abundantly; riding on horseback; the waters and climate of Leamington many times, as well as those of Cheltenham and Harrogate frequently; have lived upon sixpence a-day, so to speak, and earned it, if bodily labour may be so construed." At last he was advised to abstain from all fat and fat-making articles of diet, and in thirty-eight weeks he had reduced his weight by 35 lbs., while in twelve months he had reduced it by 50 lbs., and weighed 10 stones 12 lbs. His original dietary was "bread and milk for breakfast, or a pint of tea with plenty of milk, sugar, and buttered toast; meat, beer, much bread, and pastry for dinner; the meal of tea similar to that of breakfast; and generally a fruit tart or bread and milk for supper." His altered diet was as follows:—

Breakfast at 9 a.m. 5 to 6 oz. of beef, or mutton, or kidneys, or broiled fish, or bacon, or cold meat of any kind except pork or veal; a large cup of tea or coffee (without milk or sugar); a little biscuit or 1 oz. of dry toast; making altogether 6 oz. of solids and 9 oz. of liquids.

Dinner at 2 p.m. 5 or 6 oz. of any fish except salmon, herrings or eels; any meat except pork or veal; any vegetable except potato, parsnip, beet-root, turnip, or carrot; 1 oz. of dry toast; fruit out of a pudding not sweetened; any kind of poultry or game; and two or three glasses of good claret, sherry, or Madeira; champagne, port, and beer forbidden; making altogether 10 to 12 oz. solid and 10 oz. liquid.

Tea at 6 p.m. 2 or 3 oz. cooked fruit, a rusk or two, and a cup of tea without milk or sugar; making altogether 2 to 4 oz. solids and 9 oz. liquid.

Supper at 9 p.m. 3 or 4 oz. of meat or fish, similar to dinner, with a glass or two of sherry and water or claret; making 4 oz. solids and 7 oz. liquid. For night-cap, if required, a tumbler of grog (gin, whisky, brandy, without sugar), or a glass or two of claret or sherry.

The principles involved in this diet are quite evident. The starch, sugar, and fat of the diet are reduced to a minimum. They are, as a matter of fact, less than is sufficient for the liberation of heat and energy. Consequently, the stored-up fat of the body would be drawn upon to yield what was deficient in the diet. In the second place, the richness in nitrogenous material would stimulate oxidation changes, and, aided by exercise, would hasten the consumption of the deposited fat. The diet was successful with Banting, but as a matter of fact it is a modified starvation diet, from its deficiency in non-nitrogenous substances, and many people would find its employment attended by serious results. It is not, therefore, to be hastily tried by everyone with a tendency to stoutness. Its principles, however, may be gradually put in force and extended as the person finds his organization becoming accustomed to them. They are chiefly these: avoidance of all foods rich in carbo-hydrates, or very sparing use of them, notably potato, white bread, rice, sago, tapioca, corn-flour, semolina, sweets, sweet fruits and sweet vegetables—like carrot, turnip, parsnip, beet-root—reduction of fat, butter, cream, and abstinence from sweet wines and ales.

On the other hand, there are allowed all kinds of lean meats, lean fowl, and lean fish, eggs, game, green vegetables, succulent fruits, natural wines, bitter ale in small quantity, and spirits. Brown bread should be substituted for white. It may be added that the large quantity of wines and spirits consumed by Mr. Banting is too great for commendation.

Professor Ebstein of Gottingen has a plan which differs nothing in principle from that of Banting, but which tries to avoid its risks. "Sugars, sweets of all kinds," he says, "I forbid unconditionally. The quantity of bread is limited at most to 3 or 3½ ounces a day, and of vegetables I allow asparagus, spinach, the various kinds of cabbages, the legumes, whose value as conveyers of albumen, as Voit observes, is known to few. Of meat I exclude none, and the fat in the flesh I do not wish to be avoided, but, on the contrary, sought after. I permit bacon fat, fat roast pork and mutton, kidney fat, and, when no other fat is at hand, I recommend marrow to be added to the soups. I allow the sauces as well as the vegetables to be made juicy, as did Hippocrates, only for his sesame oil I substitute butter." "The permission to enjoy certain succulent things, always, of course, in moderation—as for instance salmon, pâté de foie gras, and such like delicacies—reconciles the corpulent gourmet to his other sacrifices. These consist in the exclusion of the carbo-hydrates."

The name of Professor Oertel of Munich is also identified with a cure for "growing too fat." It does not differ in principle from Banting's. But it allows fat to the extent of from 1 to 1¼ oz. per day, and it allows rather more carbo-hydrate, 2½ to 3½ oz. Ebstein allows 3 oz. fat per day, and only 1¾ of carbo-hydrate. Whereas, in Banting's diet, the fat was reduced to ⅓ oz. and the carbo-hydrate to 2¾ oz. per day. Oertel's allowance of albuminous food is nearly the same as Banting's, 3½ to 6 oz. per day, while Ebstein permits only 3½. The feature of Oertel's plan is a series of regular and graded exercises and gymnastics, specially by the enforced exercise of climbing heights.

Diet for Diabetes.—This has been so fully entered into on p. 303 and subsequent pages that further details are not necessary here. It may only be remarked that the diet rigorously excludes carbo-hydrates. The difficulty often is that the excess of nitrogenous diet threatens mischief to the kidneys, and one has to face the question whether a less rigorous exclusion of carbo-hydrates, by necessitating less albuminoid food, may not be less hurtful to the kidney. It is of doubtful advantage to reduce, almost to nothing, sugar expelled by the urine if the method taken to achieve this has lit up a serious kidney disease.

Diet for Gout.—Gout has been sufficiently described on p. 432. One of the chief features in gout is an interference with the due oxidation of proteids, leading to an accumulation in the system of uric acid or urates. The indication, so far as diet is concerned, is the restriction of proteid foods, and especially proteid foods derived from the animal kingdom. Fowl, fish, and milk are quite permissible in the diet, so also are sweetbreads and tripe, if taken in moderation. Of vegetable foods the gouty person should eat liberally—potatoes, carrots, turnips, parsnips, beet, broccoli, Brussels sprouts, cabbage, spinach, endive, lettuce, celery, beans, peas, kale, onions, leeks, salsify, cucumber, marrow, &c. Milk puddings are allowed, if they are made without egg. Custards and omelettes are forbidden, so also are jellies. Pastry is better avoided. Fruit puddings and fruits are suitable. A very small portion of a fat cheese may be permitted, considering its smallness. Of as much importance as the meat is the drink of the gouty person. It would appear as if, in many instances, it is the liquor that is consumed that somehow or other interferes with the proper oxidation of the nitrogenous food and provokes a gouty attack. Malt liquors, all rich and sweet wines, specially port, champagne, &c., are most injurious. Claret, whisky or brandy, and aërated water are the only alcoholic drinks of which the gouty may partake, but always in great moderation. Withal, the dieting is only of great value when combined with regular exercise. If sedentary habits are indulged in, the oxidation of the proteids will still be incomplete, and attacks, though modified, will still recur.

Diet for Rheumatism.—Flesh meat is restricted in rheumatism, and only the lighter and less rich kinds of animal food allowed, such as chicken and fish. Vegetable food is freely given, lemons and lemon-juice being specially commended. The desire is to diminish the acidity of the blood, and this is readily accomplished by a diet poor in animal food and rich in vegetable.

Diets for Invalids.

In the following paragraphs the object is to examine some of the foods which are supposed to be, or actually are, particularly nourishing and digestible, and therefore specially suitable

for those whom ill-health has rendered unable to make use of ordinary foods, however light and well-prepared. Without attempting any definition we may say that an invalid has, as a rule, a poor appetite, a weak digestion, and a marked difficulty in making good use of the food that is consumed. So that the indications that ought to be fulfilled by food for invalids is that it shall contain a large quantity of nutritive material, so that even a small quantity shall supply a fair amount of nourishment, that nevertheless it shall not tax the digestion, and that it shall be pleasant and slightly stimulating to the palate. The fulfilment of these conditions is by no means an easy matter. Let us look, first of all, at that preparation, the first and the last resource of the sick-nurse and the detestation (as a rule) of the invalid, beef-tea.

Beef-tea is usually made by cutting up the meat into small pieces, allowing it to steep in cold water for some time, then putting it into a sauce-pan and letting it simmer for some hours. The fluid parts are then poured off, the solid portions, which are tasteless and tough, and, therefore, according to popular notion, valueless, are thrown out. Now what is the value of such a preparation? *As a food it is almost valueless,* and, therefore, does not fulfil the first condition of an invalid dietary. The steeping in cold water extracts the flavouring matter of the meat, the extractives (see p. 537), and the tea has consequently all the flavour of beef, and promotes the delusion that it is nutritive. The cold water extract contains also a fair proportion of soluble albuminoid, but this is coagulated and precipitated by the subsequent prolonged simmering, and much of it is left behind when the fluid parts are poured off. Such a preparation has advantages, no doubt—it is stimulating, invigorating, and is at first enjoyed, though its constant repetition usually brings aversion—*but it is not nourishing.* We have seen that lean beef (for fat meat invalids cannot digest) contains as its principal nutritive material (see p. 543) nitrogenous materials, that is proteids, the myosin of the flesh. If beef-tea is to be worth anything as food it must contain as nearly all of the albuminoids of the beef as is possible. There is only one way of effecting this, and it is by reducing the meat to a pulp, preferably by scraping. Take 1 lb. of lean beef. If it is in one thick slice it will be more easily scraped. Let it be scraped by a knife, and the scrapings removed to a jelly-can. The process is tedious and laborious, and excessively tiring to the wrists. If it is properly done the whole of the red portion of the beef will be reduced to the finest pulp, so fine that when diffused in water it will not be perceptible to the tongue, and the tendinous, fatty, and stringy parts will be left behind, but completely stripped of red flesh. To this pulp in the can add 2 imperial pints of cold water, that is one breakfast-cupful to each ¼ lb. of beef, and a very small quantity of salt. Place the jelly-can, uncovered, in a sauce-pan of hot water, put a tight-fitting lid upon the sauce-pan, and place it at the side of the fire for 2 or 3 hours, *never allowing it to become so hot as even to simmer.* It is then kept in a covered vessel and used as required. After standing for a time the meaty pulp settles, so that the whole needs to be stirred before any is removed for use. Of the contents of the jelly-can none is unused. There are no lumps to be removed. The value of this beef-tea can easily be estimated, because it contains all the nitrogenous constituents of the beef, but very little fat. Before being given to the invalid it may be thickened by means of flour, rice, corn-flour, bread-crumbs, &c. Let a tea-cupful be taken in a small pan, and let the necessary amount of rice, corn-flour, &c., be stirred into it, and allow the whole to be very slowly brought just to the boiling point. It is then seasoned to taste. Where rice is used it should be cooked before being added to the beef-tea. The bringing to the boiling point does not injure the meaty portions, when in the form of so fine pulp and when kept from precipitation by the thickening. Now such a beef-tea is of a very fine delicate flavour, not of the strong taste prolonged cooking at a high temperature produces, and the flavour can be modified or entirely altered by the nourishing additions that may be made to it, so that sameness is avoided. Such beef-tea is a true food, it is easily digested because of the fine state of division of the meaty portion and because of the method of cooking, and in the writer's experience it is a most palatable and enjoyable dish.

Two breakfast-cupfuls will contain 107 grains of nitrogen, and probably 150 to 200 grains of carbon, that is not including the value of the added flour, &c.

Liebig's method of preparing beef-tea is as follows:—Half a pound of raw lean beef (chicken or other meat may be also used) is finely minced, placed in a glass or earthenware vessel with ⅞ths of a pint of water, to which four drops of muriatic acid and half a tea-spoonful of salt have been added. The whole is well stirred and then allowed to stand for an hour. Thereafter

it is strained through a hair sieve, and the sieve and residue washed with five ounces water. This is taken cold or only very slightly warmed. It contains not only the extractives, but also a considerable amount of soluble albuminoid, which, if it were boiled, would coagulate. It is not cooked at all, and the raw meat colour, smell, and taste, it possesses sometimes cause it to be objected to. Besides such home-made preparations the invalid has now at command an enormous number of prepared foods, extracts of meat, beef jelly, &c. Nearly all of them possess the qualification of being pleasant to the palate, and easily digested, for most of them contain very little to digest. With one or two noteworthy exceptions, they contain very little real nutriment. All of them are more or less rich in extractives, and thus possess stimulating characters of a high order. But stimulation is not nutrition, any more than blowing with the bellows a low dying fire can be used as a substitute for putting on more coals. The bellows may cause the embers to flare up and burn rapidly, but only the sooner to burn out. It is true that on the low fire one may place plentifully a fresh supply of coal, but it may be so low that it is unable to set fire to the new coal, and so goes out in spite of it. But then if we supply fresh coals and also use the bellows, we shall quicken the dying flame till it has got a sufficient hold of the coal to make it burn briskly without further help. Just so it is of little use to supply a beef-tea which only stimulates and gives no new supply of bodily fuel. If the patient be so weak as not to be able to make use of nourishment without aid, supply the stimulant also, so that the weak energies may be sufficiently roused to benefit by the nourishment. There seems to be no manner of doubt that many persons, exhausted by acute disease, fail to rally when the crisis is past, because they are plied with beef-teas, beef extracts, and so on, under the vain delusion that they are being supplied with nourishment, when they are practically being starved with the smell and flavour of the meat, with its shadow but without its substance.

An excellent example of this is found in the most popular, at least till recently, of all extracts of beef, Liebig's. Each pound of this substance is said to be the "extract" of 45 to 48 pounds of ordinary butcher's meat, and was at first by Liebig himself believed to possess highly nutritive power. Voit, whose name we have so often mentioned in these pages, showed by actual experiment that it failed to maintain life even for a brief season when used as an exclusive diet. This is indicated by its analysis, which shows the chief constituents to be as follows:

Albuminous constituents, 7 per cent (about ⅓ that of beef).
Extractives, nearly .... 8 ,,
Salts, ...23 ,,

It is, therefore, rich in extractives and salts, to which it owes its flavour and stimulating properties, but poor in nutriment.

A large number of other extracts are not very dissimilar. Valentine's meat juice, made by submitting steak to great pressure, and then evaporating the obtained juice in vacuo to the consistence of syrup, contains, according to the same authority, 6½ per cent of albuminoids, 1½ per cent of extractives, and 11½ of salts. Brand's essence contains over 8 per cent of albuminoid, $\frac{1}{10}$ per cent of extractives, and nearly 1½ of salts. Murdoch's liquid food contains 13 per cent of albuminoids, nearly $\frac{2}{10}$ths extractives, and $\frac{5}{10}$ths salts. Savory and Moore's fluid beef possesses 8 per cent albuminoid, 7½ of extractives, and 12 of salts. A great improvement on these, from the nourishing point of view, are Johnston's fluid beef and Kemmerich's extract of beef; the former of which contains 35 per cent of albuminoids, 1½ of extractives, and 15 of salts, while the latter shows 22 albuminoid, 6 of extractives, and 18½ of salts.

Now the difficulty of getting the nutriment of the beef into extracts such as these is the difficulty of solution. The nutriment becomes insoluble with a high temperature, such as is employed in the manufacture of most of them. One recent method of getting over this difficulty is by the use of artificial digestive agents, which convert the albumin into the form of peptone, which is soluble and not precipitated by heat. This is done by allowing the meat to be acted on by pepsin or pancreatin, both digestive agents, and then making an extract of the soluble parts. This has for invalids a double advantage. It makes the extract more nutritious, and since the albumin is either wholly or partially digested, it passes easily into the circulation without trouble to the weak digestion of the patient. Of such peptonized food or peptones there is now a great variety. Savory and Moore supply a dry meat peptone which can be conveniently added to other food. Peptonized beef jelly, peptonized chicken jelly, peptonized cocoa and milk, and so on, are made by them and other chemists. Many of them are still deficient in nutriment, and yet more valuable than the ordinary extracts. Benger's pep-

tonized beef jelly contains over 4½ per cent of peptone, and 2½ other albuminous substances. But chief of all such foods, in the writer's opinion, is Carnrick's beef peptonoids. It is in the form of a dry powder, containing only 6⅔ per cent of moisture. It contains no less than 63½ per cent albuminoid, of which 7 per cent is peptone. Besides it contains 10½ per cent fat, and 5½ salts. The makers assert it to be made of beef, reduced to powder, and fine wheat flour and milk dried to a powder. Of its highly nutritious qualities there is no possibility of doubt. Its only disadvantage is a not too agreeable flavour, which is, as a rule, not enjoyed by invalids. But then the powder may be mixed with hot water, as cocoa is, and seasoned to taste. If advantage is taken of the pleasant flavour of Liebig's extract, and a small quantity stirred in with the Carnrick's powder, a highly nourishing, pleasant, and stimulating fluid food is obtained. It can also be stirred with milk and used in other ways.

Anyone can now also prepare peptonized foods for invalids by using the pepsin powder, or pancreatin, or the liquor pepticus, or liquor pancreaticus, obtainable from every chemist. Milk, beef-tea, soups, &c., can be so peptonized before being given to invalids. All that is necessary is to bring the milk, beef-tea, &c., to a lukewarm temperature, then to stir in the powder, or liquid—pancreatin or liquor pancreaticus would be best—and keep the mixture warm for half an hour or thereby. With any of the preparations now in the market full directions can be obtained, so that no one need be at a loss how to proceed. (See below.)

The less nutritious forms of extract may still be of great value in the dietary of invalids, provided always people will remember that they are not to take the place of foods, but are to act as stimulants and excitants to appetite and digestion. They are to be used only as food adjuncts. If they are used simply to stimulate the taking of other and nutritious food, supplied with them, they will be used in their proper place, and will be of great value. If they are permitted to form the main diet of the invalid, the unfortunate will starve.

Diets for Infants.

Sufficient has been said elsewhere, in previous pages, as to appropriate diet for infants and young children. The object of these paragraphs is to point out the nature of a few of the foods offered now in great variety in the market as substitutes for mother's milk.

If mother's milk be taken as a standard, then infants' food should contain 1 of nitrogenous to every 3 non-nitrogenous constituent (see p. 615), or 1 of nitrogen to every 13 of carbon. The best known of such foods are Savory & Moore's, Nestlé's, Ridge's, Mellin's, Neave's, Carnrick's, and Benger's. The proportions of the two kinds of constituents are as follows:—

	Nitrogenous.		Non-nitrogenous.
Carnrick's	1	to	4½
Neave's	1	,,	5½
Franco-Swiss Co. Milk Food	1	,,	6½
Savory and Moore's	1	,,	7
Benger's	1	,,	7½
Nestlé's	1	,,	7½
Ridge's	1	,,	9⅛
Mellin's	1	,,	9½

In many of them not only is the proportion of non-nitrogenous material too high, but it consists largely of starchy material not easily digested by the child, and too little in the shape of fat (like the butter of milk) and sugar. In Ridge's this insoluble form of carbo-hydrate exists to the extent of over 78 per cent, in Neave's 73 per cent, in Savory & Moore's 70 per cent, in Benger's nearly 66 per cent. In Carnrick's it falls to 41½, in Nestlé's 35½, in the Franco-Swiss Company's to 37½, and in Mellin's to 18½; but Mellin's and Nestlé's, and we may say also the Franco-Swiss Company's, are too poor in nitrogen. In the matter of infants' food, also, analysis seems to show Carnrick's to be superior to the others. It contains 5 per cent of fat, Nestlé's 4½; all the others contain scarcely 2 per cent, and Mellin's barely 1 per cent. Therefore we give it as an opinion, based upon the proportion of nutritive ingredients, that Carnrick's soluble food comes nearer to what an infant's food should be than any of the others.

Besides in the form of such prepared foods, there are now other methods of administering foods to delicate children of a very reliable character. Cow's milk sometimes disagrees with children, because it forms a large curd in the stomach in process of being digested. If boiling the milk does not prove a satisfactory method of overcoming this difficulty, partially digesting the milk will. For this purpose peptic or pancreatic juice may be added to the milk, and the milk then allowed to stand for half to three-quarters of an hour in a warm place. It should not be allowed to stand too long, lest a bitter taste is developed. The peptic or pancreatic juice partially digests the casein of the milk, so that when swallowed it no longer curdles in large masses. The most reliable forms of such juices are Savory & Moore's of London, or

Benger's of Manchester. A very convenient means of predigesting milk or other food-stuff, such as home-made beef-tea, &c., is supplied by London chemists, Burroughs, Welcome & Co., in the form of peptonizing powders. They are in little tubes, each containing some pancreatin and carbonate of soda, enough for 1 pint of milk. It is advised to add ¼ of a powder to ¼ of a pint of milk diluted with a ¼ pint of cold water. The glass containing the mixture is made to stand in another vessel containing water as hot as the hand can bear for 10 to 20 minutes, before the mixture is given to the child. If it is not to be given at once, the mixture is, after the lapse of twenty minutes, brought to the boiling point to prevent further action of the ferment, which, otherwise, would go on acting, and would produce a bitter taste. By such predigesting of milk—and, as already said, any other food-stuff may be similarly acted on—serious digestive troubles may be overcome.

THE PRESERVATION OF FOOD.

In the first part of this book, in Section XIII. (p. 384), it has been shown in great detail how putrefaction and decay are the work of living organisms or germs deposited from the atmosphere, which, however, can be destroyed, or whose work can be prevented, by various means. The part played by such organisms in the economy of nature has also been indicated (p. 390). The living agents of putrefaction perform, we have seen, an indispensable work in the cycle of natural processes, whereby the lifeless, and in that condition useless, organic mass is resolved into its inorganic constituents, with their endless possibilities of reconstruction and revivification. But, from a human point of view, their range of operation is too unlimited, their attack too rigidly impartial, too universal, too regardless of the fitness of things, humanly speaking. For a large and necessary element in man's food is organized material readily surrendering to the attack of germs. Man's wanderings on the earth are not conditioned mainly, as are those of lower animals, by the quest of food, nor is the population of different regions determined by the abundance or scarcity of provision. Rather, indeed, as the population increases does the capacity of that region to maintain its inhabitants diminish. Thus it early became a question whether food could be preserved from the inroads of putrefaction, to permit of its transport from the place of abundant supply to the place of scarcity, and whether food, to be obtained in abundance only at one season, could be preserved to the season of scarcity. It must have been early observed that moisture and heat were two conditions necessary for putrefaction, and that the absence of these conditions favoured preservation. The natural preservation of grain must speedily have shown this, and the application by man to fruits, like grapes and currants, could not long be delayed. It appears, moreover, that this process had long ago been applied to animal food, for in the British Museum there are to be seen specimens of dried poultry, taken from Egyptian tombs, which are supposed to have been placed there thousands of years ago. **Tasajos** and **charqui**, or jerked beef, are varieties of meat prepared in South America by drying, after being dipped in brine. Similar to these is the **beltong** of the Kaffirs and the **pemmican** of arctic voyagers, the latter consisting of fat as well as of the red flesh and being also mixed with sugar and spice. In France in 1386 dried yolks of eggs were pounded and stored in barrels as provision for the army. In recent days similar methods have been applied to vegetables, potatoes, cabbage, carrots, cauliflowers, &c. The drying process, however, at least as applied to beef, seriously affects the meat so far as its nutritive qualities are concerned, and renders it tough, difficult of being cooked, and not easily digested. The practice of embalming shows also that the ancients understood that the decay of animal bodies could be prevented by chemical means, while the custom of swathing bodies in waxed and resinous bandages and inclosing them in leaden coffins, shows that they had some idea that atmospheric air was a principal agent in producing the putrefactive change. Nature herself indicated the power of cold to arrest decomposition. In Russia and other northern countries it is a common custom to kill fat cattle in November, when fodder grows scarce, and bury them in the ice or frozen earth till the beginning of May, and to pack poultry in tubs with layers of snow between them. The value of cold as a preserving agent was brought prominently before the public mind by the discovery of the mammoth at Jacutsk in Siberia, in a perfect state of preservation, embedded in a block of ice upwards of 200 feet high, an animal whose structure indicated its belonging to long bygone ages, and by the recovery in 1861 of the bodies of three Chamounix guides who had been carried away from the grand plateau of Mont Blanc by an avalanche forty-one years before.

So that the preservation of food by drying, by chemical means, by the exclusion of air, and by the use of cold, might almost be considered as parts of ancient history. Yet no method seems to have been extensively adopted till quite recent times. But with the development of ocean navigation and voyages of discovery the necessity of adopting some reliable methods became the spur to invention. The method of drying was too coarse in its results, and chemical means were not desirable, from the point of view of the palate. Salt, used for such purposes from the earliest times, which rendered the meat hard and indigestible, as well as less nutritious by extracting some of the nutritive juices of the meat, proved itself to possess more fatal objections to the long voyager, when out of an expedition of 961 men, 626 were lost by scurvy, the attendant of a diet too abundant in salt junk and destitute of fresh provisions. How urgent became the demand for better methods is evident from the fact, that while in the seventeenth century only one patent for the preservation of food was described, and only three in the eighteenth, as many as 117 were specified in the first fifty-five years of the present century, and since then they have been very numerous. Some of these were for drying processes, such as that by which Liebig's extract of meat, Hassal's flour of meat, Blumenthal and Chollet's meat and vegetable tablets, &c., are prepared; others were for chemical processes, such as the employment of sulphurous acid or carbonic oxide gas, or the injection of meat with chemical agents. The chief patents, as now appears, were those which proposed to exclude the atmospheric air or to employ cold. One method (Plowden's, 1807) proposed to exclude the air by incrusting the meat with some substance which would resist the action of the air, and the substance used was a hot extract of meat; another proposed to coat the meat with impermeable varnish. These failed, and we now know the reason. It is not the air in itself that effects the noxious change, but the living germs deposited from it. These already would be deposited on the meat before the coating was applied, and under cover of the impermeable coating could calmly proceed about their ravages. Augustus de Heine, in 1810, proposed to place the food in closed vessels and then to withdraw the air through a valvular aperture by a special exhausting apparatus. That method, too, was found to fail for similar reasons. In 1807, however, T. Saddington, of London, proposed to preserve fruits without sugar, by placing them in bottles, *driving air out the bottles* by heat, filling them up with boiling water, and then tightly corking them. The bottles, filled with fruit to the neck, were placed in a water-bath, the water of which was gradually heated up to 170° Fahr. Then the boiling water was poured in. For his method Saddington received a premium from the Society of Arts. Three years later, in 1810, a Frenchman, Appert, applied the method to meat, vegetables, fruit and milk, receiving as the reward of his labours 12,000 francs from the French government. Appert first partially cooked his provisions. He then placed them in strong bottles which he filled up to the neck. The bottles were then well corked, and the corks were covered with a luting of cheese and powdered lime, which he said rapidly hardened and was then able to resist the action of boiling water. The bottles were then wrapped in coarse canvas bags and placed up to the neck in a boiler of cold water. The boiler was covered and heat applied till the water boiled. It was kept boiling for an hour or more. The heat was then withdrawn, the water drawn off, and the bottles allowed to cool. "In every case," says Appert, "the exclusion of air is a precaution of the utmost importance to the success of the operation; and in order to deprive alimentary substances of contact with the air, a perfect knowledge of bottles and the vessels to be used, of corks and corking, is requisite." It is interesting at this date, and with our modern views, to read the notions that prevailed in the days of Appert. The alimentary substances were heated to drive the air out of the vessels that contained them. But to get rid of the last trace of air was a practical difficulty, and prolonged boiling was resorted to with the idea that the animal substance was thereby so altered as to render it less disposed to putrefactive change, while, at the same time, it was supposed that any of the oxygen of the air remaining in the closed vessels was thus destroyed. Thus we are told "the heat acts by indisposing the substances from entering into chemical action, and by removing all risk of ill effect from the small portion of air which the vessels may contain; while the rigorous exclusion of the external air contributes to render permanent the state into which the substances have been brought by the temporary application of heat."

Now, though Appert's method has proved of immense practical value, his explanation of it has been proved quite erroneous. For, as has been shown (p. 386), air may be admitted in

abundance to organic solids and fluids without exciting putrefaction, provided the organic impurities have been previously removed from the air by filtration, and substances which have been submitted to the operation of boiling are as eligible sites for the work of decomposition as those that have not been boiled. It is not the oxygen of the air that is the exciter of putrefaction, but the living organisms. It was not the expulsion of air produced by the boiling, for even that was not properly effected, that preserved the food-stuffs, it was the destruction by the heat of the living things; and it was not the continued exclusion of the air in itself, by sealing, &c., that maintained the preserved condition, but the barrier thus set up to the access of a new supply of active organisms. Enormous quantities of all sorts of alimentary substances are now preserved for indefinite periods by methods similar to that of Appert, greatly improved in its details. The substances to be preserved are packed in tins; a small quantity of water is added. The covers are carefully soldered on the tins, and in each cover is made a small pin-hole. The tins are then placed up to a short distance from the covers in "baths" of water, to which chloride of calcium has been added. The addition of the chloride raises the boiling point to between 260° and 270°, and thus ensures a greater degree of heat than could be obtained by water only. The bath is kept boiling for some time till the issue of steam from the pin-holes ensures the expulsion of air from the tins. Solder is then dropped on the pin-hole and the tins thus tightly sealed. They are then completely immersed for some time in the hot bath, and after being removed are placed in chambers kept at the degree of temperature most favourable to putrefaction. There they remain for some time. If decomposition ensues in any of the tins, it is evidenced by the bulging of the sides owing to the pressure of the gases of putrefaction. If the food remains sound, the top and bottom of each tin should be concave, pressed inwards by the atmospheric pressure outside and the diminished pressure, owing to the partial vacuum, within. If the soldering gives way at any part of the tin, or if, in course of transit, by bad usage, and so on, a crack be opened in the casing, or a point of a nail driven in, or if, by the action of weather, damp, &c., the paint coating of the tin having become rubbed off, the metal has been eaten into, air will effect an entrance with a rush, carrying germs of putrefaction with it. Thus a tin apparently sound may, on being opened, reveal putrid contents. Search will likely discover the secret pathway of the enemy. That the process is, however, an eminently satisfactory one, so far as preservation is concerned, is shown by the fact that stores of tinned meats, landed on the beach of Prince Regent's Inlet from the wreck of H.M.S. *Fury* in 1825, were found twenty-four years later in a perfect state of preservation by the captain of H.M.S. *Investigator*, and that in spite of exposure to extremes of weather. The extent of the industry which has been developed, aided by various modifications and improvements in the process, is of a very remarkable character. For the following statistics in reference to the industry I am indebted to the kindness of Messrs. Simpson, Roberts, & Co., of Liverpool and Halifax.

In 1885 21,255,000 pounds weight of tinned meats were imported into the United Kingdom from Australia, the value of which was about £430,000. On the Pacific Coast of North America the tinning of fish, principally salmon, is a large industry, the amount packed in 1884 being 47,294,160 in tins of one pound, and in 1885 the amount was 40,114,320 one-pound tins. Of these one-pound tins from seventeen to nineteen millions are imported into the United Kingdom annually to cheapen our fish supplies.

Messrs. Simpson, Roberts, & Co. also inform me that an average of 50,000 one-pound tins of canned salmon are consumed daily in this country, 35,000 of lobster, and probably 100,000 of beef and mutton. In Australia the industry is conducted at 19 factories, of which 4 are in Queensland, 5 in New South Wales, 4 in Victoria, and 6 in New Zealand, and the work is performed mainly by Scotchmen or men of Scotch descent, to the number of 2500 to 3000 persons. In Canada the Scotch villages on the coasts of Nova Scotia, Cape Breton, and Prince Edward Island furnish the bulk of the fishermen, and packing men, women, and girls. In many fishing villages in Nova Scotia and Cape Breton Gaelic is still found, and in many it prevails. With the Scotch villages are found French communities, which furnish clever-fingered females for the careful and tasteful filling of the lobster cans. In many instances the parish priest conducts the business arrangements of the simple Franco-Canadian peasants, and inspects during the season the conduct and progress of his flock. The value of the industry to the fishing community of Canada and Newfoundland amounts to from £250,000 to

£300,000 annually. So energetically has the fishing been pushed that the supply has rapidly diminished for two or three years past. Six years ago two or three lobsters filled a one-pound can, but in 1885 over five were necessary. Restrictive laws under such circumstances seem absolutely demanded. On the Columbia, Oregon, and neighbouring rivers the salmon fishing is carried on by white men, and the canning by Chinese labour, but in British Columbia to the north both are conducted by whites, though the Chinese are expert, cleanly workers, and more economical. In Scotland large businesses are carried on in Aberdeen, Dundee, and Leith in the preservation of meat, fish, &c.

This canned goods industry has thus, within comparatively recent years, assumed enormous proportions, and has become of vital interest to considerable populations. There can be no doubt, however, that the industry might become even more extended but for the fact that, by the methods employed, the meat is constantly overcooked, and to that extent not so much relished by the people. So far as one can gather all this superheating is for the purpose of expelling the last traces of oxygen not only from the tin but from the tissue itself. Many of the comparatively recent patents have been taken out because of some new modification that would ensure this more completely. Now it is fifty years since scientific investigators showed that the notion that the oxygen of the air was the cause of putrefaction was a delusion, yet this mistaken idea guides the practice of an industry which has practically developed since that time. The scientific facts tend resistlessly to the conclusion that absurdly high temperatures are employed in the canning process, and that the alimentary substances are exposed to them for unnecessarily long periods. I cannot resist the conclusion, from a careful survey of the facts, that if, to the undoubtedly high degree of perfection to which the mechanical portions of the operations of canning have been brought, some acquaintance of recent scientific advances in knowledge and in methods were added, some simple modifications of the process would be found, which would permit of the employment of a much lower degree of temperature, without interfering with the thoroughness of preservation.

Within recent years the agency of cold has been invoked on a very extensive scale for the preservation of food. A patent was taken out by John Lings in 1845 for employing ice in closed chambers to reduce the temperature to the proper degree. If a sufficient degree of cold is obtained the activity of the organisms of putrefaction is arrested, though the organisms are not destroyed. On the restoration of a normal temperature they become as active as ever. Following Ling's patent, others were taken out for obtaining the requisite low temperature by the evaporation of ammonia and ether. The invention of machines for the artificial production of ice gave an impetus to the employment of ice for preserving food for considerable periods. During the winter of 1875–76 large quantities of beef, mutton, and pork were brought from America preserved by ice. An effort made in 1873 to bring meat from Australia, preserved in this way, failed because the supply of ice gave out before the end of the voyage. It seemed as if there was little prospect of a trade in fresh meat being opened up between this country and so distant quarters of the globe as Australia. But in 1879 Mr. J. J. Coleman of Glasgow went out to New York with a Bell-Coleman air refrigerating machine, and proved that food could be preserved for long periods by the agency of air cooled by mechanical means. This Bell-Coleman machine is a remarkable example of the practical working out of advanced scientific theory. Its construction is based on the principles of thermodynamics, that when air is compressed heat is evolved, and that, if this compressed air be then allowed to expand, and be caused, in the act of expansion, to do work, a large amount of heat disappears. The machine, worked by steam, sucks in a certain quantity of air and compresses it to a pressure of 50 to 60 pounds to the inch. The air in the act of compression becomes very hot; it is cooled by the injection of cold water. The cold compressed air is now dried by being passed through a set of horizontal pipes, and is then allowed to expand behind a piston, which it propels in the act of expansion. In the act of doing work the expanding air becomes cooled, "as much as 50, 100, and 200 degrees below freezing point, according to the amount of previous compression." The cooled air is passed into the chamber containing the provisions, and the temperature of the air in the chamber can be kept by the machine at a constant low temperature for any length of time. With such machines no previous packing of the meat is required. The carcasses are cut up into quarters or other convenient sizes, placed in calico bags, and packed in the freezing chamber. Up to the beginning of 1883

about 4000 tons of frozen meat were delivered in Great Britain from Australia and New Zealand, preserved by the cold-air machines. As an example the following may be taken. The sailing ship *Dunedin* left Port Chalmers on the 15th February, 1882, and arrived at London Docks after a passage of 98 days. She brought 4909 carcasses of sheep and 22 pigs, all in excellent preservation, in a chamber kept cold by a Bell-Coleman machine. The sheep had been killed on the estate of the New Zealand and Australian Land Company, and were brought to the ship from a distance of sixty miles. They were hung up in the freezing chamber, and, when frozen hard, were wrapped up in calico bags and packed in layers in the lower chamber of the ship. They realized in London over £4200 more than was necessary to pay all expenses, which was equal to over 3 pence per pound for the mutton. According to the Smithfield Market reports, 27,007 tons of mechanically cooled meat, chiefly beef, arrived from the United States of America in 1884. In 1885 the total quantity of mutton received in this way from the colonies of Australia, New Zealand, and the River Plate was 777,891 carcasses, which weighed 21,930 tons.

Cold preserves meat simply because, at a low temperature, putrefactive and other germs are inert. They are not destroyed, but simply dormant, and when a normal temperature is restored they renew their activity. It has been noticed that frozen meat spoils more quickly after it has been thawed than ordinary meat. This is probably due to the fact that the process of freezing separates out water which formed part of the tissues, and that, on thawing, the water is not taken up again into the substance of the tissues, but remains simply moistening them. The meat being thus in a more moist and soft condition, permits of more rapid development and propagation of organisms. If frozen meat be thawed very slowly, however, the moist condition is not so marked, and the meat will remain longer in good condition.

Recently Mr. Coleman, in conjunction with Prof. M'Kendrick, investigated the question whether an extremely low temperature of 150° below zero or thereby, which can readily be obtained by a Bell-Coleman machine, would not absolutely destroy living organisms. They answer the question in the negative. Micro-organisms submitted even to such a low temperature as that became as energetic as ever when warmth is restored. Had the question been answered in the affirmative, it is easy to see what a new and valuable addition would have been made to food-preserving methods. It would then have been possible to seal up *fresh uncooked* meat in tins, and after a period of exposure to the extremely low temperature, to keep it, as cooked food is now kept, in tins, without any other precaution, for indefinite periods.

WATER.

Composition of Water.—Water, up to the year 1782, was considered a simple substance, but about that year the Honourable Henry Cavendish showed it to be a compound body, formed of the union of two gases, oxygen and hydrogen. He showed that when these two

gases, mixed in a certain proportion, were caused to enter into chemical union by the agency of the electric spark, drops of moisture were formed on the inner surface of the vessel. The French chemist, Lavoisier, confirmed this observation by a reverse process, namely, by splitting up water into the two elements of which it is formed. When an electric current is passed through water contained in a tube, such as is shown in Fig. 257, the water is decomposed into its elements, which appear as bubbles of gas at the terminals or poles of the wire. One gas is given off at the positive pole, namely, oxygen,

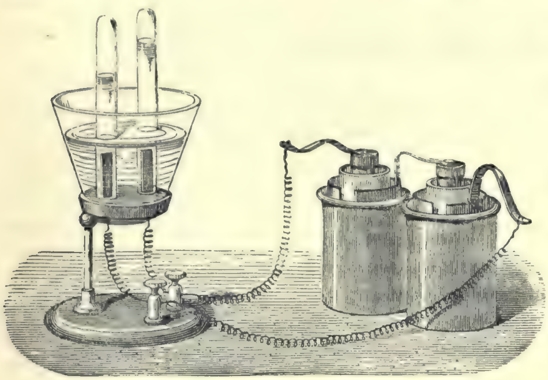

Fig. 257.—Apparatus for Decomposition of Water.

and collects in that end of the tube, the other gas, hydrogen, is given off at the negative pole, and is collected in that limb of the tube. If this experiment be performed, it will be noticed that the gas which collects on the side of the negative pole is twice as much as that which collects on the other side. Moreover, if an accurate experiment be made as to the union of the two gases in the formation of water, it is always found that twice the bulk or volume of the hydrogen is required to combine with a given volume of oxygen. If more than twice the volume of hydrogen is supplied when the union is effected, the excess of hydrogen will be found uncombined. If less than twice has been supplied, some of the oxygen will be found uncombined. Always twice the volume of hydrogen, neither more nor less, unites with a given volume of oxygen to form water, and thus the chemical formula representing water comes to be H_2O, indicating the facts that have been stated. But while two *volumes* of hydrogen unite with one of oxygen, the quantity of hydrogen is not twice the *weight* of the oxygen. For if a volume of hydrogen be taken, say a large enough bulk of it to weigh 1 lb., if an equal volume of oxygen were weighed it would be found equal to 16 lbs.; that is, oxygen is sixteen times heavier than hydrogen. Two pounds of hydrogen then unite with sixteen of oxygen, or the proportion by *weight* is 1 to 8. If then 1 pound weight of hydrogen were caused to unite with 8 pounds weight of oxygen, the result would be 9 lbs. weight of pure water. Such a thing as absolutely pure water is not, however, known. For even when pure oxygen and pure hydrogen have thus united to form water, the contact of the water with the sides of the vessel, glass, iron, &c., robs it of its absolute purity, for it would derive some minute trace of earthy matter from its touch. Distilled water contains some traces of earthy matter. Moreover, water has not only the power of dissolving solid substances, but it also dissolves gases. So that water exposed to the atmosphere takes up into solution appreciable quantities of the oxygen and nitrogen, which, in mechanical mixture, form the common air, and also of other gases, such as carbonic acid gas, which is always present in the atmosphere. Water, as we know it, always contains gases in solution, and contains also solid matters in solution, the nature and quantity being dependent upon the channel along which the water has flowed, if it be taken from a river, or the soil through which it has passed, if it be from a spring, and so on. "Pure water" is, therefore, a phrase used merely relatively, and is applied to water which possesses only such natural ingredients, in small amounts.

Physical Properties of Water.—Within a certain range of temperature, at the ordinary pressure of the atmosphere, water remains liquid. The range of temperature is, on the Fahrenheit scale, between 32° and 212°; at the former the water becomes solid, at the latter it becomes converted into vapour.

Density.—Connected with these two transformations are some extremely remarkable facts. All bodies expand and become less dense on heating, and contract, becoming more dense, on cooling. Water follows this rule only to a certain extent. On cooling its density gradually increases till a temperature is reached of 39½° Fahr. That is to say, up to this point, in a pond or lake, let us say, in cold weather, the water will undergo a process of mixing. As the water on the surface is cooled down by contact with the cold atmosphere, it becomes more dense, sinks, and allows warmer water from below to rise to

the surface, which in turn becomes cooled, sinks, and so on. Now suppose the cold were intense and long enough continued, this process might go on till the whole mass of water in the deepest lake, or sea for that matter, were reduced to the freezing point, so that the lake or sea would become frozen to the bottom, and all fish would perish. The remarkable fact, however, is that at the temperature of 39½° F., water has it maximum density. If the temperature falls below that point the water ceases to follow the rule and begins to expand, and continues to expand till the freezing point is reached. A vessel filled to the point of overflow with water at 39½° will immediately begin to run over, if the water is further cooled, because of the expansion. It is this that causes water-pipes to burst in time of frost. The effect of this on lakes, &c., is that as soon as the water on the surface becomes cold enough to be on the point of forming ice, it is of less density than the water below, and remains upon the surface. It is also a bad conductor of heat, and so it serves as a protection between the freezing atmosphere and the warmer water beneath, preventing the mass of water freezing throughout.

Latent Heat and Capacity for Heat.—A second remarkable fact is that in the transformation of water from the liquid to the solid state, a large amount of heat is liberated from the water, and when the solid ice is retransformed into liquid water, a disappearance of heat takes place to the same extent. This may be easily understood by a simple experiment. If ice be placed in water in a pot, and set on the fire, it will, of course, melt. If the temperature of the mixture be taken it is 32° F., and when the pot has been on the fire sufficiently long to cause the ice to be nearly all melted, if the temperature be again taken, it is still 32° F. A large amount of heat has disappeared, or has become "latent," as the phrase is, in the act of melting the ice. The quantity of heat which thus disappears or becomes latent in melting the ice would be sufficient to raise the temperature of 1 lb. of water from freezing point up to 174° F.

A similar thing happens when at the boiling point water becomes converted into vapour. The temperature of boiling water and of the vapour given off is the same, and yet a large amount of heat disappears in the transformation of the liquid to the gaseous condition. The heat which thus becomes latent is called the latent heat of vapour, and is so great that the heat which disappears in converting 1 lb. of water into vapour would raise the temperature of over 5¼ lbs. of water from freezing to the boiling point. In other words, 1 lb. weight of the vapour of water at the boiling point, if mixed with 5¼ lbs. of water at the freezing point, would make the water boil. It is this fact that makes it possible for one to boil water in a capsule of paper. So long as there remains any water in the paper it will not burn, for the temperature cannot rise above 212° till all the water has been converted into vapour, and this temperature is not sufficient to set fire to the paper. It is the same fact that makes steam so valuable an agent for heating purposes. For in passing back again from the condition of vapour to that of water, this enormous quantity of heat is liberated, and may be used to heat the atmosphere. In passing from the liquid to the gaseous state water expands enormously; the vapour given off from one pound of water will occupy a space 1600 times greater than that of the water; hence arises the energy of steam-engines.

It may be noted here that the vapour of water is quite colourless. It is only when the vapour passes into a colder atmosphere and begins to condense that it becomes visible as steam, or as fog, cloud, &c.

It is, moreover, the operation of the same fact in nature which prevents sudden changes likely to be destructive alike to the life of plants, animals, and man. Just as the passing off of the water, boiling in a paper-bag over a flame, into steam saves the paper from destruction, so is the earth saved from bursting into fervent heat under the influence of a hot sun by the evaporation of water from its surface, and from river, lake, and ocean. Even so is the human body saved from destruction by fire, by the fire of the combustion process going on within itself. For it has been estimated that the heat given off within the body by the oxidation of food is sufficient in 24 hours to raise the whole body to the boiling point. The evaporation of sweat from the body causes the disappearance of an enormous quantity of heat, and thus keeps the temperature at a normal level (see p. 309); on the other hand, if the passage of ice to water did not involve a large absorption of heat, a few hours of a hot sun would convert masses of snow on mountain ranges, or ice-glaciers, into torrents carrying destruction to the valleys. But the physical facts that have been stated show how the inevitable and unceasing operations of nature, as they apply even to such an apparently simple

substance as water, substitute gradual changes for sudden reversals, and combine for the comfort and continuance of the living creation. A kindred fact to that of the latent heat of water is what is called the capacity for heat of water. Suppose a quantity of lead to be placed in a pan over a fire, and the same weight of water placed in a similar pan over the same fire, the lead will become hot long before the water, because the lead has much less capacity for heat than water. This is represented in figures by saying that the capacity of water for heat in comparison with lead is as a 1000 compared with 31. To put it in another way, one could heat 32 pounds of lead to a certain degree as quickly as 1 pound of water to the same degree. Our seas, lakes, rivers, &c., become warm more slowly than would similar masses of any other substance, and they cool also more slowly, and in this way also they are natural opponents of sudden change, and are important agents in securing gradual changes of season, and in tempering alike the fierceness of summer and the rigour of winter.

The boiling point of water is 212° F. at the atmospheric pressure represented by 30 inches of mercury. If the pressure falls, as it does when one ascends in the atmosphere, water will boil at a lower temperature. Thus when the pressure falls to nearly 28 inches, water will boil at 209° F. On the top of Ben Nevis, in Scotland, 4406 feet above sea-level, the boiling point is reduced to 203°, equal to a barometric pressure of a fraction above 25 inches. If the pressure be increased, as it is if one descends a pit, the temperature of boiling rises. Moreover, the pressure of dissolved salts in water raises the boiling point. Thus common salt, to the amount of 7·7 per cent, will raise the temperature nearly 2°.

Water as a Solvent.—Water is one of the most efficient of solvents, dissolving solids, liquids, and gases, though in very different proportions: thus 1 lb. weight of cold water will dissolve 3 lbs. of cane-sugar, but the same quantity of cold water will dissolve not much more than ⅓d lb. of common salt. Hot water usually dissolves substances more readily than cold, though this is not always so. For water at the point of freezing will dissolve twice as much lime as water at the boiling point. Gases are dissolved in water very readily, some, however, much more readily than others: carbonic acid gas, the gas which gives the briskness to aerated waters, ammonia, and sulphurous acid easily, and oxygen and nitrogen with less ease. The quantity of gas that water can hold in solution depends upon the temperature and upon the pressure of the atmosphere. We all know, for example, that in hot weather aerated waters, &c., very readily burst the bottles in which they are confined, or blow out the corks. This is because, under the influence of the heat, the water has been compelled to give off the gas it held in solution at a lower temperature, and the pressure of liberated gas has become too great for the bottle. This is the reason for iced champagne. The placing of the champagne bottle among ice causes it to dissolve much of the gas free in the bottle, but imprisoned by the wired cork, and when the cold champagne is taken into the warm mouth, the gas is rapidly liberated, producing the sharp pleasant sensation. It is the presence of ordinary air dissolved in water and of carbonic acid, that gives to it its pleasant flavour. If the water be boiled the gas is driven off, and the water becomes, in consequence, mawkish and insipid. If suspicious water has been boiled for safety, the pleasant taste may be restored by shaking it up in a large vessel, and thus causing it to dissolve more air. These facts regarding the physical and some of the chemical characters of water have, perhaps, no very direct bearing on the subject of which this section treats, but they are of extreme interest, and not so widely known as they ought to be.

We must now consider some of the properties of water of more direct relationship to the point of view from which, in this section, we must regard it.

Constituents of Water.—Water, we have said, always contains some dissolved substances, picked up as it passes through the atmosphere or filters through the soil, on the quantity of which depends the estimate one forms of the value of the water for drinking and for other domestic purposes. These constituents are of two chief kinds, inorganic, derived, that is, from the lifeless world of matter, such as common salt, lime, &c. &c., and organic, derived from animal and vegetable matter.

The solid constituents of water vary within very wide limits. The following table shows the total saline material present per gallon in a variety of waters:—

	Grains per gallon.
Loch Katrine supplying Glasgow	2
Grasmere	2·92
Rydal	3·11
River Dee supplying Aberdeen	4
River Tay supplying Perth	5
Water supplied to Liverpool	5
Claremont water	5·7

	Grains per gallon.
Farnham in Surrey	7·25
Clyde	9·19
Rhone	9·112
Nile	10·9
Rhine	16·247
Seine	17·84
Thames supplying London	20
Spring water	40–60
Jordan	75
Sea water, Shores of Baltic	1100
,, German Ocean	2380
,, Open Atlantic	2450
,, Mediterranean	2870
,, Dead Sea	17,200

Of these dissolved solids, the commonest is carbonate of lime or chalk. Another compound of lime often present is gypsum, or sulphate of lime. It is these substances, along with salts of magnesia, the carbonate and sulphate, which occur also very commonly, though in much smaller proportion, that give to water what is called **hardness.** Chalk is not very soluble in pure water, but it is always more easily dissolved in water containing carbonic acid gas, which natural water always does. If by any means the carbonic acid be driven off, the water cannot contain the lime in solution to the same extent, and thus some of it is precipitated in a solid form. Boiling thus expels the gas, and it is carbonate of lime, thus precipitated, that forms the crust so common in boilers. If a great quantity of lime be present this water may become milky by the precipitation. Water flowing among hard granitic mountains contains a small quantity of such saline material, a small fraction of a grain per gallon, while in well water, particularly in chalky districts, the quantity may rise to over 20 grains per gallon. Thus, what is said to be the purest of waters is that of the Loka, in the north of Sweden, which flows over insoluble granite rocks, and contains only $\frac{1}{10}$th of a grain per gallon of solid matter. In Bala Lake, North Wales, there is less than $\frac{1}{4}$ grain of lime and magnesia salts per gallon. Loch Katrine water is exceedingly soft, containing only a little over $\frac{1}{2}$ grain of lime per gallon, and $\frac{1}{10}$th of magnesia per gallon. The waters of the various London Water Companies contain 8 or more grains of lime per gallon, and from $\frac{3}{10}$th to $\frac{8}{10}$th grain magnesia, and are, therefore, hard waters. Deep well waters are usually hard waters, containing a higher percentage of these ingredients than either river or lake water. In mine waters the quantity is still greater. Such waters are not well fitted for domestic purposes, cleansing operations being performed with difficulty. Nor are they as a rule agreeable to the taste, being somewhat harsh, though they are commonly bright and sparkling. The lime causes soap to curdle, and a lather cannot be formed till sufficient soap has been used to combine with the excess of lime, so as to render the water soft. Thus they are always extravagant in the consumption of soap. Of all ordinary waters, rain water contains least of such saline substances, therefore it is so soft, and desired in districts where the water, supplied for domestic purposes, is hard. The curdling of soap by hard water is made use of as a test of the degree of hardness. A solution of soap is used and added to a definite quantity of the water, till a lather be formed and remains for five minutes. The hardness is then expressed in degrees. Thus, water, which requires ·012 of a pound of best hard soap to 10 gallons before a lather will remain, is water of 1° of hardness.

How to soften hard water becomes, then, a question of some importance. One method, already explained, is by boiling the water. A second process is that of Dr. Clark, of Aberdeen. His process consists in the addition of quicklime to the hard water, 1 ounce of quicklime to 1000 gallons of water for each degree of hardness. This may seem a strange way of getting rid of the hardness, by adding more of the very agent which one desires to get rid of. The explanation is that the quicklime forms with the carbonic acid a fresh supply of carbonate of lime. The carbonic acid being thus removed, this carbonate of lime is precipitated, and with it the carbonate of lime originally present, and kept in solution by the free carbonic acid gas. The carbonates are allowed to subside and the water run off. This method is employed by manufacturers using enormous quantities of water, but it is not possible for householders. If the hardness is caused by sulphates of lime or magnesia, boiling, &c., will not remove it. The addition of common washing soda, till the water seems to appear milky, will, in this case, soften it, because the sulphates are converted into carbonates by the soda, and are precipitated. Water so softened must not, of course, be used for drinking or cooking purposes.

There is an idea that very soft waters, such as that of Loch Katrine in Scotland, are not so wholesome, because of the absence of lime salts, as others which contain them in more abundance. The latter have been supposed to be more useful, in the case of children, for

example, for the growth of bone and so on. There does not seem to be any substantial ground for such an idea. When one considers the quantity of water drunk per day, one can see that a very insignificant amount of lime could be introduced into the body in this way, and lime salts are better supplied in the ordinary way of food. The addition of lime water to milk or drinking water, for such purposes is, the author believes, a serious mistake, as the lime is apt to be precipitated in the bowels, and to interfere in other ways with the due process of digestion.

Common salt, or chloride of sodium, also is found, as a rule, in ordinary water, though in very small quantities, 1 or 2 grains per gallon. It is the presence of this small quantity, however, that causes the milkiness to appear, if a drop or two of solution of nitrate of silver (lunar caustic) be added to the water, the cause of the milkiness, for example, in the washing of photographic prints. A large quantity of this substance in water, unless it had been from near the sea-shore or from a well in the neighbourhood of deposits of salts, would make one suspicious of admixture of sewage, which invariably contains common salt in solution. Sea water is, of course, rich in common salt, containing over 2000 grains per gallon. The Dead Sea contains nearly 8500, while from Elton Lake, in Russia, two hundred thousand tons of salt are annually obtained.

Salts of potassium are also found in ordinary water in minute quantity, and traces of iron. Mineral waters contain various metals, but these will be mentioned in the paragraphs devoted to such waters.

Besides these substances, which are wholly derived (the exception about common salt having been noted) from the inorganic world, there are other solid substances of a saline nature, derived directly or indirectly from organic bodies, and demanding very special heed. These substances are nitrates and nitrites, compounds of nitrogen with sodium, potassium, or calcium, as nitrate of soda, nitrate of potash, or nitrate of lime. The nitrogen of these compounds is derived from animal or vegetable substances. The presence of such salts in the water indicates, that at one time or other, animal or vegetable matter gained entrance to the water, it may have been in the form of sewage, and that, by a process of decomposition, the organic matter has been broken down and resolved into inorganic substances. This process is performed by the agency of the oxygen dissolved in the water and derived from the atmosphere. The organic substance, in fact, undergoes a species of oxidation, of burning, by which its organic form is destroyed. Now, the presence of nitrates or nitrites is not in itself injurious. They are harmless, provided they do not exist in excessive quantities. The presence, however, of the decaying animal and vegetable matter itself would be injurious, and, but for the process of oxidation, water to which it had gained access would always be threatening to health. The presence of nitrates and nitrites, therefore, is indication of previous contamination of the water, though it does not necessarily imply unwholesomeness of the water. In wholesome water no more than traces of these substances should be present, not more than 0·35 grains in 100,000, according to Hassall.

Gases dissolved in Water.—Gases are present in water in solution. The chief gases are oxygen and nitrogen, obtained from the atmosphere, but oxygen in greater proportion than is found in the air, because water dissolves it more readily than nitrogen. "Twenty-five gallons of water will contain about five pints of these gases," consisting of rather less than two of oxygen and rather more than three of nitrogen (Attfield). Carbonic acid gas is present, usually in considerable quantity; thus twenty-five gallons of water may contain one or even two gallons of dissolved carbonic acid gas, according to circumstances, for carbonic acid gas is very readily soluble in water. Carbonic acid gas is also a product of the oxidation of organic matters present in the water. Just as the nitrogen unites with oxygen and bases, such as sodium, to form nitrites or nitrates, so the carbon of the organized body unites with the oxygen in the water, the atmosphere being an ever-present store whence the water may derive fresh supplies. If carbonic acid gas is an indication of organic material having been present in the water, it is also an indication that nature's purifying process of combustion has been going on, and that the possibly hurtful organized body has been reduced to harmless simplicity. The presence of these dissolved gases gives to water a pleasant sharpness. Without them water would be tasteless and insipid, as water always is which has been boiled, because the heat has expelled the dissolved gases.

Impurities in Water.—**Organic.**—The chief impurity in water is organic matter, which may be present in the water in suspension merely, or in solution. This organic matter may be derived merely from dead and decaying vegetable struc-

tures, washed into the water of a stream, for example, by the rain, or from dead animal matter also, undergoing gradual decay in the fields and ditches, or in the stream itself, or it may be derived from human excreta and the refuse of human habitations, owing to the opening of sewers into the stream, or owing to the trickling of the liquid from a dungheap, for example, finding its way into a well. Of all sources of pollution, the last is the most serious. Now, the nature of the impurities thus cast into water will be readily understood. To take one illustration, urine contains in solution (see p. 292) chiefly urea, a nitrogenous body, the product of the oxidation of albuminous food-stuffs in the body, uric acid, also a nitrogenous body, common salt, phosphates of soda, and other compounds of phosphoric acid, sulphates, &c. Now, if sewage is gaining access to a water supply to any extent, common salt, phosphates, and sulphates, will be found in the water in greater quantity than is usual in ordinary water, derived from the urine, and the unusual quantity of these inorganic, and in themselves harmless, constituents would raise suspicions in an analyst's mind as to the purity of the water. Further, he will be able to detect the presence of a substance containing nitrogen, derived from the urea and uric acid. If he can determine in what form the nitrogen is present, he will obtain a good idea of its source. Everyone knows that if urine stands for a time, it decomposes, becomes muddy, and gives off an offensive ammoniacal smell. This is because, under the influence of atmospheric organisms, the urea becomes converted into carbonate of ammonia. All the urea might thus become transformed, and be no longer found as such; but the fact that an organic body had been present would be signified by the detection of the ammonia, which is formed of the nitrogen formerly existing as urea, and originally derived from albuminous food. With the lapse of more time, further changes would occur, still further altering the form in which the nitrogen existed; these changes being due, as already noted, to oxidation process, the tendency of all the change being to break down hurtful organic bodies into harmless and simple inorganic substances. Albuminous substances themselves gain access to water, and may be detected by the chemist as such, but they undergo in course of time the same transforming process by the agency of the dissolved oxygen of the water. Thus in searching for impurities in water, the chemist tests for albuminoid substances themselves. If they exist beyond the barest trace, that implies that the water is contaminated with material which nature has not yet had time to reduce to simple and harmless forms. Such water is not fitted for domestic purposes, unless purified by some means, and stands, therefore, condemned. Should, however, his tests fail to find such organized material he tests for ammonia, for nitrites, for nitrates, in short, for the substances which would result from the presence of organic impurity, if there had been time for oxidation to occur. If these are found, in any amount, the fact that at some part of its course the stream is contaminated is established, although before it reached the place where the water was taken for analysis nature had had time to effect her purifying processes.

Now, the mere presence of albuminoid material or of its oxidized products does not necessarily render water impure. There is no manner of doubt that such polluted water is continually being used for domestic and drinking purposes, and without harm often resulting. It is not even the quantity of such impurity that determines the unwholesomeness of the water, for one well may be largely contaminated with sewage, and may be consumed without doing any perceptible injury; another, in its neighbourhood, may be so slightly contaminated, that the detection of any impurity in it is a matter of difficulty, and yet it may bring disaster to every household using it. It is the exact nature of the organic pollution that makes the difference, a difference which may be absolutely undetectible by the most delicate tests, and yet may be appalling in its results. Take an illustration: a farm possesses a well, in the immediate neighbourhood of which the dungheap is foolishly permitted to lie. All the waste water and excreta from the farmhouse, all the manure from the stables and byre, &c., are thrown on this heap. The watery portions from the heap filter through the ground and gain access to the well. The water of the well is used by the people of the farm for their own domestic purposes, for washing milk-cans, and so on. This state of things may last for years and no one be apparently any the worse of the polluted state of the well. But one of the farm hands takes typhoid fever and is nursed at the farm. The excreta from the patient are also thrown on the heap, and filter into the well. The pollution of the well is not altered in *quantity*, it is no more than it has been for years, but it is altered in *character*. A peculiar character has been imparted to it, marked by

an outbreak of typhoid fever among those to whom the milk from the farm is distributed, because the milk has become in turn polluted by the water, used to wash the milk vessels or to mix with the milk. No chemist could detect by any test whatever the poisonous character that had been imparted to the well. He could determine that it contained organic impurity, but he could do no less, perhaps only a brief month before, when the water was apparently harmless. Perhaps if things are simply allowed to go on, as they often are, the patient dies or recovers, no more typhoid excreta are thrown upon the heap, though the excreta of the dwelling are consigned to it as before, water still filters into the well as before, and pollutes it as much (in quantity) as before, but its death-dealing power disappears and it becomes again harmless. Still to chemical analysis it yields no indication of difference. When it is impossible to distinguish between an organic impurity which is harmless, and one which is harmful, there is only one means of obtaining safety, and that is to declare as unfit for use any water which contains organic impurity to any appreciable extent, and entirely to condemn any water in which even a slight trace of organic impurity appears to be due to sewage pollution.

Gaseous Impurities in Water.—Ammonia, being derived from organic bodies, has been already referred to as an impurity. Sulphuretted hydrogen is also derived from the oxidation of organic substances. Sulphurous acid gas and various other vapours may be derived from the atmosphere, and are frequently found in rain water. Their presence depends on the kind of chemical works, manufactories, &c., in the neighbourhood. Carburetted hydrogen is another gaseous impurity sometimes found.

Metallic Impurities in Water.—Water is sometimes contaminated with lead, zinc, copper, iron, and arsenic. These are generally derived from cisterns or pipes for either storage or distribution of water. Rain water may contain zinc or lead from zinc lining the roof from which the water was collected. Arsenic may be derived from the atmosphere. The common contamination, however, is from lead. The purest water, that which contains least saline ingredients, and is consequently very soft water, is that which most readily acts on the lead piping. Water which contains organic matter, nitrite of ammonia, and chlorides, also readily becomes impregnated with lead. On the other hand, waters rich in carbonic acid gas and hard waters themselves afford the best protection, for the carbonic acid forms with the lead an insoluble carbonate, and this coating the metallic surface prevents further action on the metal. In the same way carbonates, phosphates, and other salts form a coating. It appears, however, that an excess of carbonic acid will redissolve some of the carbonate of lead, and thus waters, aerated waters, for example, highly charged with carbonic acid, are open to metallic contamination. Acids derived from organic substances, such as fruits, vegetables, beer, &c., act strongly upon lead, and water containing such impurity readily acquires also metallic contamination. The result of drinking water containing lead to any amount is symptoms of lead-poisoning, of which one of the earlier is lead colic, and one of the later is lead paralysis. Cases of lead-poisoning have arisen, according to Dr. Angus Smith, from as little as $\frac{1}{100}$th grain per gallon; but some persons are more susceptible to the action than others. According to Parkes any quantity over $\frac{1}{20}$th grain per gallon should be considered dangerous. It may be noted that water in cisterns may acquire lead from a leaden cover, with which the water does not make contact. Vapour of water spontaneously rising from the cistern condenses upon the lid. It is thus distilled water, acting most readily upon the lead, of which it dissolves some portion, and the drops falling back into the cistern carry lead in solution with them. The cistern should, therefore, be provided with a wooden or slate cover.

The Various Kinds of Water differ in the quantity and kinds of their constituents.

Distilled Water is comparatively pure. It is entirely free of mineral constituents such as chlorides, carbonates, sulphates, &c. It is prepared by placing the water in a vessel or boiler, fitted with a tight lid, from the centre of which a metal tube arises. The tube is prolonged and coiled to economize space. The heat applied to the boiler raises the water in vapour, which as it passes through the tube, or still, as it is called, condenses to steam, and then to water, which issues in drops and is caught in a receiver. To quicken the process the tube is surrounded by a tub through which cold water flows, thus quickly condensing the steam. From the water in the boiler the gases quickly pass off and may be allowed to escape before the water is collected in the receiver. If, however, the water employed contains ammonia in solution, or as carbonate or nitrite, it will be given off and be readily dissolved again by the condensed steam; so that unless proper precautions are taken, the distilled water may not be free of ammonia.

The water may also contain other impurities, readily given off as vapour to contaminate the distilled water. It is necessary, therefore, to employ water as free from organic impurity as possible. The first portion of the distillate ought always to be thrown away in any case. Further, the process should not be carried on till all the water in the boiler is driven off, lest some of the residue be blown over into the condenser. Distilled water is largely produced from sea water in sea-going vessels, thus getting rid of the difficulty of storage, and of the risk of the stored water undergoing changes and suffering harm from the tanks in which it is kept.

Distilled water is not at all palatable, owing to the absence of dissolved gas. This is overcome by re-aerating the water, mixing it again with air, for which purpose special apparatus has been devised, one in common use being that of Dr. Normandy.

Distilled water, containing as it does no solids, is peculiarly apt to dissolve minute quantities of the material of the pipes through which it passes. Lead pipes are particularly liable to attack, and lead-poisoning has frequently been produced in this way, not only from pipes themselves, but from the joints of the distilling apparatus. The boiler should be of earthenware, iron, or copper, the pipes of earthenware or tin, and the condenser of the same, copper pipes and condensers being avoided. Zinc pipes should also be avoided.

Rain Water, if proper arrangements exist for its collection and storage, ought to be a very pure and soft kind of water. It never can be absolutely pure, for in its descent through the atmosphere it will dissolve gases of the atmosphere, as well as solid matters floating in the air, and it will also wash down with it floating matter which it may yet be unable to dissolve. What the nature of the dissolved and suspended matter is will depend, accordingly, upon the nature of the atmosphere through which it falls, and the constituents of the rain water will afford an indirect method of determining the nature of the atmosphere. In country places, devoid of manufactories or large collections of houses, it will be purest; and in manufacturing districts and in large towns it contains considerable impurity, both of an inorganic and organic kind. Nitrogen and oxygen gases it will contain in solution, and also carbonic acid gas, but in very small proportion compared with well waters, for the atmosphere contains only 4 parts of this gas in 10,000. Sulphurous acid, hydrochloric acid, nitric acid, ammonia (free and in combination), &c., will also be in the atmosphere, derived from chemical and other works. Organic impurity, swept down from the air, is also present in larger or smaller quantity, derived from animal emanations. Thus Dr. Angus Smith states the amount of free ammonia and albuminoid ammonia found in the rain water of various localities, of which a few samples are given:—

In rain obtained at Valentia, Ireland, there were	0·180	parts of ammonia	per	1,000,000.
,, ,, at west coast of Scotland	,,	0·484	,,	,,	,,
,, ,, ,, ,, England	,,	1·900	,,	,,	,,
,, ,, in London	,,	3·450	,,	,,	,,
,, ,, ,, Manchester	,,	6·469	,,	,,	,,
,, ,, ,, Glasgow	,,	9·100	,,	,,	,,

The albuminoid ammonia in rain water varied from 0·034 parts per 1,000,000 in Valentia to 0·105 on the west coast of Scotland, 0·251 in Manchester, and 0·3 in Glasgow. Of inorganic constituents sulphates amounted to 0·1911 grains per gallon rain water at Valentia, 2·9 in Manchester, and 4·9 in Glasgow. The contrast between the state of the atmosphere in Valentia and in Glasgow is very strikingly shown in such figures as these. Near the sea, salt is acquired from the atmosphere. In the country, 2 grains per gallon is about the average quantity of all the constituents of rain water. To this, however, must be added varying quantities dependent upon the mode of collection. If it has come into contact with limestone walls, roofs, &c., chalky substances will have been acquired; if with tile roofs, vegetable matter is likely to be present, because of the low forms of vegetable life usually found on such roofs; if it has been collected on a zinc-lined roof, lead contamination may be present. Slate roofs are least apt to yield any notable addition to its constituents. Further, care must be taken with the pipes through which it passes, as its freedom from constituents makes it readily attack lead, and with the cisterns in which it is stored —slate cisterns being the best, or cisterns made of brickwork, set in cement and plastered over with it. The gutters along which the water flows to the tank should be cleaned at regular intervals. It is advisable not to allow the first portion collected after dry weather to be run into the cistern; and for drinking purposes it

should be filtered, through three or four feet of clean gravel, and then through one or two feet of charcoal. This not only removes impurities, but also aerates the water. Rain water is highly desirable for domestic purposes because of its softness, and is, when the precautions indicated have been followed, less likely to be contaminated than other kinds, and most wholesome and palatable.

Ice Water is comparatively pure. In the process of freezing the gaseous and saline ingredients are separated out, so that ice formed of salt water is yet free of the salt and very pure. Water obtained from melted ice is flat and insipid because of the absence of gas.

Snow Water is for a similar reason very pure. There is a popular opinion that water obtained from melted snow is unwholesome. There is no ground for this view, for when melted it is as good for quenching thirst and as wholesome as other kinds of water, though the absence of gas renders it less palatable.

Well Water is rain water which has passed into the soil, and filtered its way through it till it reaches the level at which the ground is saturated. The soil acts as a sponge, absorbing and retaining within its interstices water, more or less according to the nature of the soil. In its course the water dissolves much of the earthy constituents it meets with, and the exact nature of its mineral constituents will consequently depend on the strata through which it passes. Usually well waters are hard waters, because their prolonged passage through the soil has permitted them to dissolve much calcareous and other material they have come into contact with. Thus 15 to 25 grains per gallon is a common amount of solid matter for deep wells in the chalk, which yield as a rule wholesome and pleasant water. Now, in its course through the soil the water will carry with it much organic material, from decaying vegetable or animal matter on the surface, perhaps from manure spread over the surface, and so on. If the water percolates far enough through the soil this organic matter is all destroyed, oxidized, burnt, in its passage. It undergoes chemical union with the oxygen contained in the ground air, in the pores of the soil, and ceases to be organic substance as such. The products of this combustion, in the form of nitrates, are in the water, but are harmless. If this be understood, it explains at once the difference between the water of shallow and of deep wells. The former collect water which has passed through only a few feet of soil, sufficient perhaps to deprive it of all muddy appearance, so that it looks clear enough, but not sufficient for the oxidation changes to be completed. Surface wells are always to be regarded with suspicion, especially if in the neighbourhood of habitations, whether for man or beast, as it is almost certain some of the surface drainage will gain access to it. Deep wells may be polluted in the same way, the water which rises up in the depths of the well being perfectly pure, but the manner of building the well permitting surface water to soak into it from above. For the purpose of preventing this, if the well is built of brick a good facing of cement is most useful. If the well has been polluted, it is difficult to get rid of the contamination, even after all further access of impurity has been prevented. A considerable time must be allowed to elapse, and the natural process of purification may be aided by removing as much of the water as possible on several occasions. Deep well waters are usually sparkling and pleasant to taste from the abundance of carbonic acid they contain. This carbonic acid is produced as the water finds its way through the soil, because the carbon of the organic material, undergoing oxidation, unites with the oxygen of the air in the soil, and carbonic acid gas is formed. Deep well water is usually brought to the surface by pumping; and pump water and deep well water signify commonly the same thing.

Spring Water is the same in its nature as ordinary deep well water. The fact that the water *springs* is due entirely to mechanical conditions. The water issuing from a spring at the surface, whether the surface be a natural one or one artificially produced, as, for example, in digging a well when a spring is come upon, has its gathering ground at a higher level than its point of issue. But it has been prevented sooner reaching the surface by impervious strata of earth; and when at last it is able to flow up to the surface, it comes with a rush more or less marked according to the difference of level between its point of outflow and its gathering ground. If, at the point where it flows out, one were to build a wall round it, it would rise in the cylinder thus formed, until it reached a height equal to that of its gathering ground, wherever and at whatever distance that might be. One would then have a well, only above instead of below the surface level. If, through long-continued drought, the level of water in the gathering ground fell, the height of the column of water in the tower would fall also; and if, by long-continued rains, the level of the former rose, that of the latter would rise also.

This is the explanation of intermittent springs. The level of water in their gathering ground is not always so high as to keep a continual outflow at the spring. It is only after heavy rains at the high ground that the spring flows out, and when, after the rains have ceased, the level of the ground water at the high land falls, the overflow at the spring ceases.

Artesian Wells (Fig. 258) are bores passing often great distances into the ground, through impervious strata, and tapping streams, flowing through the lower pervious layers, whose gathering grounds are much higher than the surface of the bore. When the stream is thus tapped the water rises in the bore and overflows on the surface because of the difference in level. This is represented in the figure, where D taps water in the pervious stratum C C kept from reaching the surface A by the impervious stratum B B.

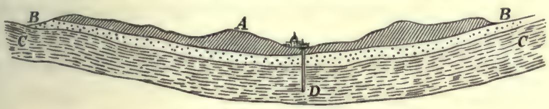

Fig. 258.—Artesian Well.

One of the earliest of such wells was in the French village of Artois, hence the term Artesian. The well at Grenelle, Paris, is 1800 feet deep, and contains a large quantity of carbonates of sodium and potassium.

River Water is rain water collected from the uplands, with additions perhaps from springs, and, as it flows through the lowlands, with additions of surface water from fields, waste and sewage from farms, villages, &c., on its banks. Its quality will be very different near its source from what it is near the sea. In the high lands it will contain ingredients washed down into it from the hillside, and gained as it passes through glens and ravines. But such water is likely to be extremely wholesome and pleasant. Any organic substance in it is not likely to be productive of harm, being derived from natural sources; and, besides, in the course of the water downwards, the combustion of the organic material occurs; and as it is broken up into spray and mixed with air in tumbling over cascades and dashing into foam in its irregular broken channel, it is undergoing a rapid process of purification. But, as the river flows through cultivated and highly-manured fields, and receives a large quantity of impurity from farms, &c., it becomes difficult for its purity to be maintained. The water is not so freely exposed to and mixed with the air, and its organic impurity is not so readily burnt off. If manufactories crowd its banks, and sewage from towns is cast into it in quantity, purification by natural means becomes almost impossible. River water, therefore, unless when taken high up the stream, is almost invariably contaminated, and forms an exceedingly unsafe source of supply.

Lake Water varies in composition according to the district over which the rain water and streams formed by it flow. When the lake is in an upland, surrounded by hills, from whose streams it is supplied, and when the hills are of hard formation, with little limestone, and when the lake has full and easy outlet by streams, the water is of a very pure and wholesome character. For the mountain streams in their descent dissolve little material, and the free outlet prevents the accumulation of solid material in the water. A lake like the Dead Sea, with little outlet but by evaporation, becomes highly charged with saline ingredients, for the evaporation continually causes concentration. Mountain lakes with free outlet form the most valuable sources of water supply, provided they are free of impurity from human habitations. A good illustration is Loch Katrine in Scotland, supplying Glasgow, which contains only 2 grains of solids per gallon; Thirlmere in Cumberland and Bala in Wales contain about the same amount. The total solids yielded by five gallons of Loch Katrine water might be heaped on a threepenny piece. Waters derived from peaty districts are often discoloured and flavoured by suspended matter derived from the peat, which is not, however, hurtful, and is easily separated by filtration. Such waters are often less pleasant, because of the smaller quantity of dissolved gases they contain; but these can be imparted to them by filtration through gravel and charcoal beds, which also improves them by permitting the process of combustion to occur, and thus removing traces of organic matter. In course of transit through iron pipes such waters undergo an improvement.

These various kinds of waters have been classified, as regards quality, by the Rivers Pollution Commissioners as follows:—

Wholesome	1. Spring water.	Very palatable.
	2. Deep well water.	
	3. Upland surface water.	Moderately palatable.
Suspicious....	4. Stored rain water.	
	5. Surface water from cultivated lands.	Palatable.
Dangerous...	6. River water to which sewage gains access.	
	7. Shallow well water, to which sewage gains access..................	

Sea Water is rich in salts, specially chloride of sodium, common salt. Of this salt the water of the British Channel contains over 2000 grains per gallon; magnesium salts are also present in considerable quantity, and salts of lime. Sea water contains also bromine and minute quantities of iodine and fluorine. The richness in salts is supposed to be due to the continued inflow from rivers, &c., of waters containing them in solution, which is never returned from the sea, as it loses only water by evaporation. Organic matters from vegetable and animal life present within it and derived from tributaries also, of course, abound, and gases are also present in solution. The composition of sea water varies in different places, according to the character of contributions made to it by rivers, and for other causes.

The Detection of Impurities in Water.—The determination of the nature and quantity of the various constituents of water is the business of the expert chemist, and the examination of one sample just sufficiently to enable him to say whether it is wholesome or not will occupy many hours, while its exact analysis will occupy days. In taking water for the purpose of sending it for analysis, persons should be careful to take a fair sample. The bottle used should be thoroughly cleansed, and after it is quite clean it should be rinsed out several times with the water that is to be collected. Care should be taken that the stopper is also quite clean. In the case of service pipes, the water should be taken if possible direct from the main. River water should be taken well in the stream, the bottle being plunged overhead. The best bottles are what druggists call Winchester quarts, of which two had better be sent, filled up to the neck, though one such quart would be sufficient for a partial analysis. The source of the water—well, river, lake, &c.—should be stated, as well as any circumstance as to situation of well, depth, surroundings, that may seem to have a bearing on its purity.

While a careful analysis is a very laborious proceeding, involving much knowledge and practical skill, it is yet possible for anyone to make a few rough tests with water that will suffice, for the time being, to indicate whether the water is subject to any marked impurity. For example, any householder might roughly satisfy himself as to the character of the water taken from a well attached to a country house where he wishes his family to holiday; and so on. The chief points to be noted are stated in the following paragraphs:—

Colour of the Water.—The water is taken in a long glass cylinder, standing on a white porcelain plate, and the plate looked at through the column of water. The colour of pure water is a greenish-blue, but it requires a mass of it, perhaps a depth of something like 10 feet, to show it clearly. But the column of water in a tube two feet long even will reveal any suspended matters giving other colour to the water. Mere traces of peaty matter and other material in suspension will be revealed in the brown appearance the porcelain plate will have when viewed through the column.

Odour of the Water.—Pure water has no perceptible odour. If any smell is detected the water is to be regarded with suspicion. A simple method of testing consists in filling an ordinary water-bottle to within a third of the top, with the water, closely covering the top with the palm of the clean hand, vigorously shaking the water, and then sniffing up with the nose thrust well into the mouth of the bottle, the hand not being removed till one is ready to insert the nose at once. If a bad smell is perceived, the water is impure. If no bad smell is perceived, the water is not necessarily pure. A more searching test consists in warming the water in a stoppered flask up to 100° Fahr., shaking it, and then suddenly removing the stopper and smelling it. Decaying animal and vegetable matter will be indicated by a bad odour. The same test may be applied, though not so quickly, by corking up some of the water in a clean bottle and setting it aside in a warm place for a day or two, then shaking the water and smelling it.

Flavour of the Water.—Not much can be learned from this. The purest water is the most insipid, from the absence of gases, and the best flavoured water may contain considerable organic impurity. Excess of salts will be readily detected; thus in the case of wells near the sea, the entrance of sea water gives a brackish taste.

To detect organic impurity in the water, there are two tests that may be employed with perfect ease. One is Nessler's test, the other is the test with permanganate of potash. The former detects ammonia in the water, and ammonia, as we have seen, is one of the products of the burning in the water of organic substances, so that the detection of ammonia by Nessler's test indicates that organic matter has previously gained access to the water, though it has had time to undergo change. The latter test is used to indicate whether there yet exist in the water organic substances not yet oxidized, still in a state of change, for this

would be a much more serious impurity than the former. In analysts' reports these two kinds of impurity are signified by the terms "free ammonia" and "albuminoid ammonia." The analyst determines first the quantity of ammonia existing as such in the water. He then wishes to know how much organic matter as such is present. To determine this directly is not an easy matter, and so he falls upon the expedient of chemically acting upon any organic matter the water may contain, so as to produce ammonia from it, and then he finds it easy to determine the quantity of ammonia so produced, and hence to calculate the quantity of organic substance that must have been present to yield it. Hence the use of the phrase "albuminoid ammonia."

Nessler's Test is ordered to be prepared as follows:—35 parts of iodide of potassium are dissolved in a small quantity of *distilled water;* a saturated solution of bichloride of mercury is now added, little by little; a red precipitate appears, which is almost immediately dissolved. In continuing to add, a point is at last reached when the precipitate commences to be insoluble. Sufficient bichloride solution has then been added, and the liquid is filtered. To the filtrate 120 parts of caustic soda (or 160 parts caustic potash), dissolved in water to a strong solution, are added. The total quantity of liquid is then made up to 1000 parts. Finally 5 parts of a saturated solution bichloride of mercury are added, to clear up the solution and make it sensitive. On standing a deposit appears, from which the clear liquid should be decanted into a large stock bottle, well corked. For use a small bottle should be used, filled from the larger as required to prevent frequent opening of the stock bottle, which would render it cloudy.

Now place some of the water to be tested in a clean glass, and add a very small quantity, a drop or two of the Nessler solution. Allow it to stand, covered, in a good light. The appearance of a yellow colour indicates the presence of a small quantity of ammonia. If a dark yellow be produced, still more a brownish colour, and still more if a yellow precipitate forms, the presence of ammonia in quantity is indicated. Nessler's test is said to indicate by the colour the presence of ammonia, should even so small a quantity as only 1 part of ammonia be present in 20,000,000 parts of water. And as the ammonia can readily be concentrated by distillation, the presence of only 1 part in 200,000,000 parts of water is said to be detectible by Nessler's test.

The Permanganate Test is applied by taking the water to be tested in a glass vessel, and adding about a tea-spoonful of weak sulphuric acid, then dropping in a few drops of a weak solution of permanganate of potash, and stirring with a glass rod. The permanganate is to be added till a rich rose-colour is acquired by the water. The vessel is then covered with a clean glass plate and allowed to stand in a good light. If there is any quantity of organic matter present the colour will go in a few minutes. A few more drops of the permanganate may be added, and the time that elapses before the colour is again destroyed noted. For the purpose of comparison a similar vessel containing distilled water may be set alongside the water to be tested, and coloured with the solution, and this may be used as a standard, as it should retain its colour, by which to judge of any change in the colour of the water being tested. The permanganate solution is robbed of its colour because it readily yields up the oxygen it contains to any body capable of becoming oxidized by it. Thus the organic matter seizes upon the oxygen, undergoes combustion, and becomes destroyed in the process. The quantity of the solution of permanganate requiring to be added time after time before the rose-colour is permanently obtained may, therefore, be made a measure of the quantity of organic material present in the water: the more organic matter, the more oxygen needed for combustion, and, therefore, the more permanganate decolorized. The results of the permanganate test require, however, to be taken with some reservation. Nitrous acid, commonly present in water, will also destroy the colour. Now nitrous acid indicates previous contamination of the water, that is organic impurity which, however, has undergone already partial destruction, and is not so serious a constituent as actual organic matter. Iron also destroys the colour. Good drinking water, such as Loch Katrine, will, however, have no perceptible effect on the colour till after the lapse of 24 or more hours, showing merely traces of organic material. Thus an ordinary analysis of Loch Katrine water shows of free ammonia 0·004 parts in 1,000,000, and of albuminoid ammonia 0·08 parts per 1,000,000.

If two tests mentioned, when applied to a particular sample of water, indicate organic impurity, a rough confirmatory test may be sought by applying the test for chlorides; for if sewage is gaining access to water, the quantity of chlorides is certain to be increased be-

cause of the quantity of chloride of sodium, common salt, in urine. The test is a drop of nitric acid and then a few drops of a weak solution of nitrate of silver (2 grains to the ounce are sufficient). This with good water will give a faint cloudiness, for a small quantity of chlorides is always present; but if there is a marked white precipitate produced, the evidence of sewage pollution is almost conclusive, always under the condition that the water has not been taken from near the sea-shore, where salt water could gain access to it.

The Detection of Lead in Water.—To the suspected water add a few drops of nitric acid, mix with a glass rod, then add a drop or two of sulphuretted hydrogen water. A very faint trace of lead will be revealed by a brown discoloration of the water. The delicacy of this test is exceedingly great. It will indicate the presence of 1 part of lead in 100,000,000 of water.

The Microscopic Examination of Water often reveals the presence of vegetable and animal matter, dead and living. By this means one will often be able to detect undoubted evidence of sewage contamination, owing to the presence of undigested remains of food, derived from excreta, fragments of vegetable tissue, starch grains, fragments of muscular fibre, and so on. Besides these, living forms are found in river water, water from ponds and marshes, surface water in general, and sometimes in the water of shallow wells. They are readily found in water contaminated by sewage, and they never occur in water of deep wells and springs, that are not polluted. Their presence is sure evidence of a dangerous pollution. These living forms belong to a great variety of species, desmids, diatoms, confervæ, infusoria of many kinds, animal forms of the worm family, and bacteria or germ forms. A drop of water from any stagnant pool abounding in decaying vegetable matter will show such things in multitudes. The presence of such living things in water—of all of them, or of any one kind of them—does not imply any special unwholesome character. It indicates that the water is impure, is being contaminated in various ways, and that opens up a vista of endless possibilities. The figure (Fig. 259) is one modified from Hill Hassall, who was the first to direct attention to the importance of the microscope in the examination of water.

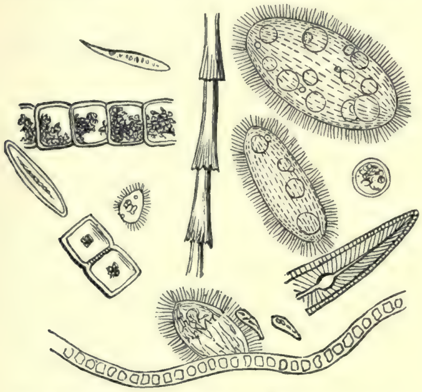

Fig. 259.—Some Animal and Vegetable Structures found in a Drop of Thames Water.

The Purification of Water.—**Filtration.**—The chief means of purifying water is by filtration. Now filtration acts in two ways. It acts obviously as a mechanical obstacle to the passage of matter contained in the water not in solution but in suspension. Consequently, water impure simply from the presence of earthy particles, peaty substances, and so on, which give a brownish tint to the water, is rendered quite clear by passing through the filter. But filters, specially the filters of gravel, sand, charcoal, and spongy iron, and the like, used for water filtration, act also chemically. As the water slowly finds its way through the pores of the filter, which are occupied by air, it meets with oxygen and the process of combustion goes on, so that the water that has passed through is purified, not merely because suspended matters have been removed, but also because some organic impurity has been consumed. Further, the water becomes aerated in its course through the filter, by taking up not only air, but carbonic acid produced in the oxidation process. Water companies filter the water they supply in large paved tanks provided with perforated tubular drains, which are covered by several feet of gravel, coarse at the bottom and becoming fine at the top, while over the gravel is a layer of sand several feet deep. The water is slowly and regularly admitted to the tank, the depth of water being never very great, in order that the water may not be forced through. For filtering purposes, however, nothing is equal to pure well-packed animal charcoal, which removes organic impurity much more thoroughly than other materials. The silicated carbon filter, magnetic carbide of iron filters, and filters of spongy iron are also very reliable. Slow filtration through a layer of animal charcoal, in coarse powder, 4 inches thick, will, according to Wanklyn, purify river water containing a considerable quantity of organic impurity. After being used some time the charcoal needs

renewal or cleaning. It may be cleaned by washing it first with a solution of permanganate of potash (10 to 15 grains to the pint of distilled water, with a few drops strong sulphuric acid), then in dilute hydrochloric acid (60 drops to the gallon of water), and then in pure water, afterwards drying it. Merely exposing the charcoal to the open air for some hours will destroy the organic impurity it has retained, or exposing it to a considerable heat.

Filters for Domestic Use.—Two kinds of filters are shown in Figs. 260 and 261. The latter consists of a block of carbon through which the water requires to pass to get from the upper to the lower vessel. The former is a

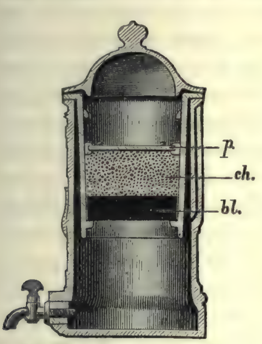

Fig. 260.—Cleansible Filter.

Fig. 261.—Glass Table-filter.

specimen of one kind of filter, of which there are now many in the market, which are easily cleaned. The large earthenware jar contains within it a smaller one containing the filtering apparatus. The latter is formed of a block of carbon (bl), and above it a layer of granulated charcoal (ch), kept in position by a porous earthenware plate (p). All these parts can be removed for renewal or cleansing. The water is poured into the upper part of the inner jar and passes through the filtering beds to the space below.

Domestic filters require attention to secure constant cleanliness. It is to be feared that many filters are used year after year, without ever being cleaned. Under such circumstances they are more likely to render the water that passes through them impure than to purify them. Even when the organic impurity in the filtering water is small, the filter should be cleaned or renewed every few months, and oftener if the water contains much contamination. Many filters require returning to the makers for cleaning, others may be renewed and cleaned by any one with ease. Parkes gives the following directions for the cleaning of filters to avoid taking them to pieces:—Every two or three months (according to the kind of water) air should be blown through, and if the charcoal be in the block form it should be brushed. Then 4 to 6 ounces of the pharmacopœial solution of potassium permanganate, or 20 to 30 grains of the solid permanganate in a quart of distilled water, and 10 drops of strong sulphuric acid should be poured through, and, subsequently, a quarter to half an ounce of pure hydrochloric acid in 2 or 4 gallons of distilled water. Three gallons of distilled or good rain water should then be poured through, and the filter is fit again for use. If the filter can be taken to pieces the charcoal can be spread out in a thin layer, and exposed for some time to the air and sun, or strongly heated in an oven.

A simple filter for domestic use may easily be made with a flower-pot. The lower part is filled with coarse pebbles, over which is placed a layer of fine pebbles, and above that a layer of clean coarse sand. On the top of this, place a piece of burnt clay perforated with small holes, and cover it with a layer, 3 or 4 inches thick, of well-burnt pounded animal charcoal.

Clarification of Water by Alum, Oak Chips, &c.—When it is suspected that a considerable quantity of organic impurity is present it is well to boil the water before it is filtered. It may afterwards be mixed with air by agitation. Another method of purifying water consists in adding to it something which will clarify it, as white of egg is added to jelly for the same purpose. Alum has specially been used for this purpose, of which 6 grains is added to each gallon of water. The action is most effective when the water contains carbonate of lime, the sulphuric acid of the alum leaves it to combine with the lime to form sulphate of lime, and the alumina, which is insoluble, is precipitated, carrying with it suspended matter.

If the water contains little lime carbonate, if, that is to say, it is very soft water, it is advised that a little chloride of lime and carbonate of soda be dissolved in it before the alum is added. The sediment is then allowed to settle and the clear water drawn off. In a similar way will the addition of some astringent substances cause a purifying of water, such as chips of oak. Thus the muddy water of the Nile is clarified by rubbing the inside of the water vessel with bitter almonds, and in India the Hindoos rub the inside of the water-jar with the fruit of the *Strychnos potatorum.* The fruit is beaten into a paste, of which about 30 grains are used for 100 gallons of water, and it is allowed to act for 24 hours. Or one of the

seeds is simply "rubbed for a minute or two round the inside of the vessel containing the water, generally an unglazed earthen one," and in a very short time the impurities fall to the bottom leaving the water clear and apparently wholesome. It is chiefly used for river water at the season when it is laden with suspended matters. Probably the effect produced upon the bitter waters of Marah by casting in the tree was similar to that of alum, oak chips, or the fruit of *Strychnos potatorum*.

Purification by Condy's Fluid.—When water contains a large quantity of organic matter, more than a filter can readily dispose of, and when no other water is easily procurable, it may be made tolerably safe and wholesome by means of permanganate of potash. Parkes advises as follows:—"In the case of any foul-smelling or suspected water, add good Condy's red fluid (that is, a solution of permanganate of potash), tea-spoonful by tea-spoonful, to 3 or 4 gallons of the water, stirring constantly. When the least permanent pink tint is perceptible, stop for five minutes; if the tint is gone, add 36 drops, and then, if necessary, 30 more, and then allow to stand for six hours; then add for each gallon 6 grains of a solution of crystallized alum, and if the water is very soft, a little calcium chloride and sodium carbonate, and allow to stand for twelve or eighteen hours. If not clear or if discoloured, filter through charcoal." In any case it will be well to filter through charcoal, as some of the organic matters may not be oxidized by the permanganate, and the filtration through charcoal may remove them.

Finally, it has been already mentioned how by boiling, or by the addition to water of a little unslaked lime, hardness of water may be greatly diminished, and how, by the addition of common soda, all hardness may be removed. The latter, however, must not be added to water to be used for drinking or such purposes.

Impure Water as a Cause of Disease.—Impure water may be a source of disease in a double way. It may produce simply a bad state of general health through its effect upon the digestive system, stomach, bowels, &c. Thus, there seems no doubt that vague ill-defined digestive troubles, dyspepsia, diarrhœa, sickness, dysenteric conditions, and so on, may arise from the use of impure waters. Such conditions may very often have such a cause when it is least suspected. It appears, moreover, that waters containing simply excess of inorganic salts, very hard waters, may occasion disturbance referred to the bowels, constipation, and so on. But, in the second place, water may be the medium of conveying specific disease. There is now no manner of doubt that water affords a medium for the propagation of typhoid fever and cholera, owing not to simple organic impurity, but to the specific poison of the disease gaining access to the water in sewage, containing the excreta of patients suffering from such diseases (see p. 187). Goitre has been shown to be associated with a particular kind of water (see p. 210), and various malarial diseases have their home in marshy places, where there is insufficient vegetation to employ the resources of the soil (see p. 427). Moreover, various forms of intestinal worms may be propagated by the ova of the worms gaining entrance to the water. This is illustrated in detail on p. 170. Now there is really no means of determining, as already stated, when an organic impurity in water is simply unpleasant and undesirable, and when it contains a specific poison capable of occasioning an epidemic. This is exceedingly well put in the following paragraphs from Wynter Blyth:—"Nothing is more clearly proved than the fact that a large population may drink a sewage-polluted water with the utmost impunity, under certain conditions. A few years ago the author proved that a town in Somersetshire had drunk a water-supply from shallow wells which was nothing more nor less than dilute sewage; and yet the death-rates from fever, from dysentery, and all other diseases supposed (and rightly supposed) to be propagated by water, were remarkably low in comparison with places drinking a pure water. Here, then, was an experiment ready made on more than a thousand persons, and the negative results recorded for the best part of a century. It proved that under ordinary conditions the water was harmless, and yet what chemist could pass such? The colour, taste, and smell, as well as the organic carbon, nitrogen, and microscopical characters, all combined to show that the characters of the supply were of great impurity; on the other hand, water of very moderate impurity, as shown by ordinary chemical and microscopical investigation, has many times been as fatal as a solution of some subtle poison. These, as it were, unconscious experiments continuously proceeding in towns, in villages, and in solitary homes, demand the closest study; and such a study will, in years to come, make clear the apparent discrepancy often existing between chemical and biological analyses. Possibly the conclusion already

shadowed forth is this:—Water, however polluted by healthy human or animal sewage, nasty and abominable liquid as it may be, will produce no disease; water infected with the excretions from diseased natures will cause disease.

"Since, however, at the present time we cannot differentiate between those excrementitious matters which cause disease, and those which do not cause disease, *it is clearly safest to condemn as a supply a liquid which has been proved to be contaminated by a something, which, for ought we know, contains the seed of typhoid fever or of cholera.*"

Aerated Waters are waters which contain gas dissolved in them, so that the term might be applied to ordinary water, since it contains oxygen, nitrogen, and carbonic acid gas in solution. The term, however, is restricted to those waters which contain gas dissolved in them in such quantity, that when they are exposed to the ordinary atmosphere the gas comes off in bubbles, giving a sparkling quality to the water. Water is capable of dissolving any kind of gas to greater or less extent, but the most readily soluble of the ordinary gases is carbonic acid gas, and it is with this gas that the majority of aerated waters are charged. There are some natural waters, such as those of Seltz, Vichy, and Spa, which contain carbonic acid gas in such quantity that they effervesce in the open air, and such waters are called **natural aerated waters.** The carbonic acid gas is derived in their case from the ground, in which it exists in some districts in large quantities, specially in volcanic and limestone districts, being collected often in large volumes, because of difficulty of escape, and being, therefore, under great pressure. It is found at the bottom of deep wells and mines, in caverns, &c. Collections of it in mines are called "choke-damp," because of its suffocating character. The term "aerated waters," as commonly employed, however, means water which has been designedly charged with gas, usually carbonic acid, for the production of a pleasant sparkling beverage; and it is these **artificial aerated waters** that we shall consider here.

First of all it is needful to state a few of the characters of the gas.

Carbonic Acid Gas is produced wherever carbon or carbon-containing substances are burnt, being formed by the union of carbon with oxygen, in the proportion of one combining weight of carbon to two combining weights of oxygen, and it is, therefore, represented by the chemical formula CO_2. The gas consists, in round numbers, of 28 per cent carbon, and 72 per cent oxygen. The gas is also produced as a result of chemical changes going on in living structures, both vegetable and animal, the product of combustion occurring within them, ending in the liberation of heat and energy (see p. 527), and is given off in the gases of respiration as a waste product. Carbonic acid gas is likewise produced in all processes of fermentation

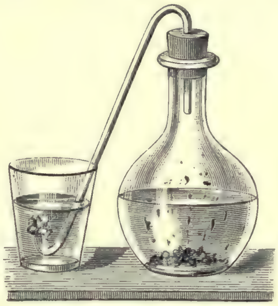

Fig. 262.—Arrangement for producing Carbonic Acid Gas.

and putrefaction. The ordinary processes of decay of animal and vegetable substances have as their ultimate object the oxidation or combustion of the complex organic body, and its consequent reduction to simple substances. This we have seen goes on in water, by the agency of the dissolved oxygen, and goes on by simple exposure to the air, even as it goes on, though with much greater rapidity, in a coal fire. In the course of fermentation it is one of the products, and it is because of its production that fermented beverages have their brisk, sparkling character, the gas being prevented from escaping. Carbonic acid gas may be readily produced in quantity, by acting on chalk or marble with dilute hydrochloric acid, or by heating chalk or marble to redness in an iron or earthen retort. Fig. 262 shows a very simple arrangement, which any one could make for himself, for the production of the gas. Into the flask is placed some marble, broken small, and then some muriatic or hydrochloric acid—spirit of salt, it is also called—diluted with water (1 part of the acid to 10 of water would suit). The gas at once proceeds to come off. The flask is now corked with a tightly-fitting india-rubber cork, through which passes a glass tube. The tube is bent downwards, and may dip into a vessel of water, through which the gas will then be seen to bubble. If, instead of ordinary water, the vessel contains lime water, as soon as the gas begins to bubble

through it, it will become milky, through the formation of carbonate of lime, which will not dissolve in water, and so is precipitated as a white powder. To make certain that the gas is obtained pure, instead of the vessel of water, substitute a second flask like the first, half fill it with pure water, and let the tube from the flask generating the gas pass through the cork, nearly to the bottom. Let a second tube pierce the cork, not being prolonged far into the flask. The gas will pass into the water from the first tube, bubble through it, being washed in course, and will collect, purified, in the upper part of the flask, from which it will escape by the second tube, and by a prolongation of the tube may be led wherever one wishes.

Carbonic acid gas is a heavy gas, more than $1\frac{1}{2}$ times heavier than air, and it will consequently displace air, just as water will, and may be poured like water from one vessel to another. It is, however, colourless, and therefore invisible, and one, therefore, cannot tell when a jar has been filled with it. A very simple test will, however, settle that question. Suppose one wished to collect a jarful of the gas: all that is needful is to take the jar, or say a large wide-mouthed bottle, with a glass stopper, such as druggists employ, and having made certain of its cleanness, pass the tube coming from the apparatus, described above for washing the gas, down to the bottom of the bottle. The gas flows in, as water would, displacing the air. As soon as the bottle is full, it will flow over as water would. If a lighted taper be held close to the mouth of the bottle, as soon as the gas begins to flow over, the taper will be extinguished. The jar is then full, and if the stopper fits well and is securely fixed, its edges being slightly greased with lard to ensure perfect closure, the gas may be kept any time.

The extinction of the taper is due to the fact that the gas is incombustible. It is the product of combustion, and will not support combustion. Combustion cannot go on without oxygen, and as soon as the taper is surrounded by an atmosphere of the gas it receives no oxygen and therefore goes out. It is consequently a gas which, if breathed in any quantity, or if present to any great extent in the atmosphere inhaled, interferes with respiration, slowly, rapidly, or instantaneously, according to the extent to which it is present. It is, we have said, a heavy gas, and therefore collects at the bottom of wells, pits, &c. A man descending into such a well, without precaution, would be plunged into an atmosphere of the gas, and would at once fall unconscious, being extinguished like the candle flame. If the test already indicated were applied, and if the man, before deciding to descend, lowered a lighted candle, he could find by its extinction, or its continuing to burn, whether it was safe for him to descend. Not only does it interfere with respiratory processes going on in the body, when inhaled, but it also exerts a directly poisonous influence on the nervous system, so that an atmosphere containing plenty of oxygen for respiratory purposes would yet be poisonous, if it also contained a certain proportion of carbonic acid gas. (See next Section.)

Carbonic acid gas is very soluble in water, a certain bulk of water being able to dissolve an equal bulk of the gas. So that if a pint of pure water be introduced into a pint bottle filled with carbonic acid gas, the gas will all be dissolved in the water. The gas, like other gases, may be compressed, that is, when submitted to pressure, it can be made to occupy a smaller space. If a graduated cylinder, fitted with an air-tight piston, be filled with the gas, and then the piston pressed down with a pressure equal to that of the atmosphere, the gas will be compressed to one-half its bulk. If the piston were to be relieved of pressure it would be forced back to its original position by the expansion of the gas. Suppose the original pressure of the atmosphere is trebled, the volume of the gas would be reduced to a third. Now, even in this compressed state, water will dissolve its own bulk of carbonic acid gas, so long as the pressure is maintained. Thus, suppose a jar, fitted with a piston, and holding 4 pints of gas, and suppose at ordinary atmospheric pressure a pint of pure water to be introduced, the water would dissolve its own bulk of gas, namely, 1 pint. Suppose now a pressure equal to 15 lbs. to the square inch to be applied, that would reduce the 4 pints of gas to 2 pints, 1 pint of which (its own bulk) the water would dissolve, and thus the piston would come down half-way in the jar, the remaining half being occupied by the pint of water with 2 pints of gas dissolved in it, and the pint of compressed gas representing 2 original pints. Or suppose at first the pressure on the piston had been equal to four times the atmospheric pressure, that would have reduced the bulk of the gas to 1 pint, and this 1 pint would be dissolved by the pint of water, so that with this pressure the piston would sink to the level of the surface of the water, all the gas being dissolved. Under great pressure, then, water can be caused to dissolve a very large quantity of carbonic acid

gas. If the pressure be diminished, a proportion of the gas will be given off, and, if all the extra pressure be removed, all the gas will be evolved with effervescence, except what the water would dissolve under ordinary atmospheric pressure. Even this may be driven off if the water is heated. The reason of the effervescence of aerated water as soon as the cork is removed is evident from these explanations, as well as the bursting in summer weather of bottles containing such water.

The various aerated waters in common use consist of water charged under pressure with carbonic acid gas, to which also some particular flavouring agent has been added.

In aerated water manufactories the gas is prepared in large cylinders from chalk by the action of an acid. It is then purified by being passed through a series of vessels which rid it of foreign gases, the last of the vessels containing pure water. Thence the gas is passed to a gasometer of large size, where it is stored under a pressure of several atmospheres. From this gasometer the gas is carried by a tube to a cylinder in which pure water is contained. The gas is mixed with the water by agitation under pressure, and a sufficient quantity of gas forced into the water till a permanent pressure of twice the ordinary atmospheric pressure is reached. Simple aerated water, which is frequently called soda water, is this water charged with carbonic acid gas, without any other addition. It is run into bottles by means of a special tap and other arrangements, which prevent the escape of the gas. By means of the bottling machines now in use, the water can be bottled with extraordinary rapidity and little loss. During all the stages of the manufacture the mode of transference of gas from one cylinder to another is arranged to prevent any atmospheric air gaining admittance. Into the charged cylinder the appropriate quantity of bicarbonate of soda, potash, &c., can be introduced, if actual aerated soda water or potash water is required.

Soda Water.—As already explained, many people speak of soda water when they mean simply aerated water. Actual soda water contains 30 grains of bicarbonate of soda to every imperial pint of water, that is, each ordinary bottle, which holds $\frac{1}{2}$ pint, should contain 15 grains of bicarbonate of soda in solution. The British Pharmacopœia directs that the quantity of gas with which it is charged should sustain a pressure of seven atmospheres.

Potash Water should contain 30 grains carbonate of potash to each pint.

Lithia Water contains 10 grains carbonate of lithium per pint.

Lemonade is simply aerated water passed into a bottle, into which there has been previously put a small quantity of syrup, flavoured with lemon. There are many other drinks, exactly similar in character, varying only in the flavour which has been imparted to the syrup, such as gingerade, orangeade, and drinks flavoured with raspberry vinegar, and other fruit syrups. Gingerade is usually slightly coloured, and has added to it some mucilaginous material, which prevents the too speedy escape of the gas when it is drawn, and thus causes the more permanent "head" to appear, which the public thinks the appropriate quality of gingerade in particular.

Ginger Beer is really an alcoholic beverage, and is considered under alcoholic drinks.

Oxygenated Water, that is water which is charged with oxygen under pressure, has recently come into use, and it is said to have an exhilarating effect, and to be useful in cases of diabetes, as well as in some forms of indigestion, sluggish liver, and so on. Water, it is to be noted, dissolves oxygen much less freely than carbonic acid gas.

These aerated waters are pleasant beverages possessing little properties beyond that of ordinary water. The escape of the gas produces a sharpish, pleasant taste, and has a gentle stimulating action on the stomach, while the gas itself is somewhat soothing, and is often exceedingly grateful in cases of irritable stomach.

Contamination of Aerated Waters.—The quality of aerated waters depends naturally upon the quality of the water used in their manufacture. Aerated waters may, therefore, be very unwholesome, owing to organic or other impurity, if the manufacturer has not been scrupulously careful as to the source and condition of the water used. Supposing, then, that the water is pure, the risk is contamination with lead, for carbonic acid gas very readily attacks lead, and if in any part of the apparatus, used for the manufacture, a lead joint or a lead surface of any kind is exposed, the water will rapidly dissolve some of the metal. Lead poisoning from such sources are not by any means unknown. Tinned copper cylinders are usually employed in the manufacture to prevent this. But further contamination may arise from the syphons in which aerated waters are now so commonly sold, or gazogenes in which aerated waters in small quantities are made in households. The attachment of the

glass tube which passes down the inside of the syphon, being often made of pewter, leads to this risk.

The detection of lead in aerated water may be made in the way noted (on p. 648) for its detection in water.

Mineral Waters.—These being medicines rather than beverages, are discussed in the part devoted to drugs.

TEA, COFFEE, COCOA, CHOCOLATE, &c.

Tea, coffee, cocoa, and many other substances used for the preparation of drinks, have several common features, of which it may be well to take general notice before considering each of the substances in detail.

1. They all contain an active principle, or alkaloid, containing nitrogen, akin to the active principle atropin, of the deadly nightshade (belladonna), akin to strychnine, to quinine, and to nicotine, the active principle of tobacco. In the case of tea this active principle is **thein**, in the case of coffee it is called **caffein**, and in the case of cocoa, **theobromin**, but the two former are apparently identical.

2. They all possess an aromatic oil, on which the flavour or aroma of the infusion depends. This oil does not exist in the substances in their fresh state, but is produced in the drying and roasting processes followed in their preparation for the market.

3. Tea and coffee contain an astringent substance, tannin in the case of tea, and a modification of tannin in the case of coffee. It does not exist in cocoa, or at least is present only in very small quantity.

4. Besides these there exists a variety of substances which are of no moment from the point of view of those who are considering their value as beverages, however interesting they may be to the analytical chemist. These substances are albuminoids, gum, dextrin, fat, wax, colouring matters, woody fibre, and mineral matters.

The active principle, aromatic oil, and astringent substance are worth fuller consideration.

Thein, or **Caffein,** for the two are identical, was discovered in coffee-berries in 1820. It had been previously discovered by Leeuwenhoeck, whose remarkable microscopic work has been referred to on p. 385, but had been afterwards overlooked. It is found not only in the coffee-bean but also in the leaf of the coffee-plant. In tea it was discovered in 1827, but it was not till eleven years later that the active principle of coffee, which had been called caffein, and that of tea, which had been called thein, were found to be one and the same substance. In 1841 the active principle of cocoa was discovered. It very much resembles thein. It is owing to the presence of this active principle that all these substances possess their stimulating property. Other substances used in a similar way to tea, coffee leaves, for example, Maté or Paraguay tea, and the kola-nut, also possess the same active principle as tea. "It is remarkable," says Attfield, who discovered the presence of thein in the kola-nut, "that the instinct of man, even in his savage state, should have led him to select, as the bases of common beverages, just the four or five plants which out of many thousands are the only ones, so far as we know, containing thein."

Thein can be obtained in fine white needle-shaped crystals, and may be easily separated by anyone who cares to take a very little trouble. Put a few finely-powdered leaves into the bottom of a clean cold test-tube, add a little water, and boil over a spirit-lamp till the water is nearly all driven off. Add a pinch of dry magnesia, and mix with the leaves, with the aid of a glass rod, into a sort of paste. Then gently warm the bottom only of the tube in the flame of the spirit-lamp. The thein will be driven off and will be deposited on the upper cold part of the tube in fine needles, where the naked eye will be able to perceive them, and a magnifying-glass will make them very distinct. The same process may be carried out in a tea-spoon over a gas flame, a slip of cold glass being held over the spoon to condense the crystals.

Thein has no smell but a slightly bitter taste. Its effects upon the healthy human body have been tested directly. In small doses it accelerates the pulse and the breathing, and quickens ordinary muscular movements. It increases the action of the skin, and apparently also of the kidneys. It also excites the nervous system, quickening thought. In fact it produces in small doses those effects, the experience of which has led a cup of tea to be the unfailing resort as a cheering and gently-stimulating beverage. It diminishes the tendency to sleep and removes some forms of headache. In large doses it acts as a poison, producing nervous excitement, trembling of hands and arms, and restlessness, and ultimately narcotic effects. A dose of 4 grains is fatal to a cat, nervous symptoms being prominent. A full tea-spoonful of tea would yield from 1 to 3 grains of thein—probably on an average about 2½ grains.

Theobromin is chemically related to thein. Its

poisonous action is not so pronounced, though 15 grains proved poisonous to kittens.

The aromatic oil of tea is of a citrin-yellow colour, with a strong aroma of the tea. It is produced in the drying of the tea, by some unknown chemical change the processes induce. The oil is volatile. In the case of coffee it is produced during the act of roasting; and if the roasting be unskilfully done, the oil produced may be driven off. Persons who roast their own beans require a little practice to enable them to hit the point when the highest degree of flavour has been produced, and the least given off. Many people wonder why the coffee gave out such a delicious odour when being roasted, and why the infusion was so devoid of flavour —the reason being that they had dissipated the essential oil in the atmosphere. The essential oil of cocoa is also a product of the roasting. It is contained in smaller amount than in tea or coffee. The action of the aromatic oils has not been very thoroughly investigated, but Johnston thinks that, besides conferring the aroma on the tea, coffee, &c., it most likely exercises a narcotic influence, rendered probable by many known facts. "Among these I mention the headaches and giddiness to which tea-tasters are subject, the attacks of paralysis to which, after a few years, those who are employed in packing and unpacking chests of tea are found to be liable; and the circumstance that, in China, tea is rarely used till it is a year old, because of the peculiar intoxicating property which new tea possesses. The effect of this keeping upon tea must be chiefly to allow a portion of the volatile ingredients of the leaf to escape. And lastly, that there is a powerful virtue in this oil is rendered probable by the fact, that the similar oil of coffee has been found by experiment to possess narcotic properties." The essential oil of coffee gently stimulates the skin and bowels, and also the nervous system.

The astringent constituent of tea is tannin, a constituent also of oak bark and many other plants. It is this ingredient which produces the bitter astringent taste, so well marked specially in a long-standing infusion. It also confers upon tea somewhat of a constipating effect, more notable when tea is used strong and dark. It has been supposed to be the tannin also which makes tea rather apt to produce indigestion, but Dr. Roberts of Manchester is inclined to think that this property is due to other acid constituents, and not to the tannin. It is quite certain, however, that if strong black tea, long infused, be habitually taken, the tannin exercises an injurious influence on the mucous membrane of the stomach, owing to its astringent action. Caffeic or caffeo-tannic acid is the modification in which the astringent principle is present in coffee, though it is contained in considerably less quantity than the tannin of tea. In some cocoas tannin is present in exceedingly small amount, and in others apparently not at all.

We shall now consider tea, coffee, &c., separately, their general features, possessed in common, having been noted.

Tea is the product of a plant, *Thea sinensis*, belonging to a section of the genus *Camellia*, of the natural order *Columniferæ*, of which there are three main varieties, *Thea viridis* (Fig. 263) and *Thea bohea* (Fig. 264), native to Bengal and parts of China, and *Thea assamica*, native to Assam. The two former supply the China teas, and the latter Indian teas. The plant, it is believed, was really introduced to China from India, as early as the sixth century of the Christian era. In the eighth century it was introduced to Japan, and in the beginning of the seventeenth to Europe, and about the middle of the seventeenth century it reached Britain. The plant is a hardy evergreen flowering shrub, five or six feet high, though by cropping the upward growth is kept down to about three feet, and the lateral growth thus encouraged. If left alone it would grow to the dimensions of a tree. The plant is grown from seed, sown in March, the seed being kept during the previous winter in moist earth. The year-old shrubs are planted out in rows, a space of three or four feet intervening between each row. The leaves are not removed till the fourth or fifth year. Thereafter three or four crops are taken each year, the first in early spring, the second at the beginning of May, the third about the middle of June, and the fourth in

Fig. 263.—Thea viridis.

Fig. 264.—Thea bohea.

August. The first leaves, however, are the finest, and have the most delicate flavour. The leaves of the later gatherings are larger, more woody and bitter. The qualities of tea vary much, according to the period of the gathering, and according to the climate, soil, and other circumstances, the preparation of the leaves for the market very materially affecting the quality. The leaves are plucked by hand, women and girls being employed in the work. Four pounds of the green leaves yield one pound of dried tea. The mode of treating the fresh leaves depends on whether green tea or black is to be produced, the difference being one simply of preparation. To obtain green tea, the fresh leaves are spread out in thin layers on flat bamboo trays for from one to two hours, to allow them to dry slightly. They are then thrown into roasting-pans, heated over a wood fire, where they are moved rapidly about and become moist and flaccid and give off considerable vapour. In a few minutes they are transferred to a table, where they are rolled by hand. A second time they are put into the pan, over a slow charcoal fire, in which they are kept in rapid motion by hand, and in from an hour to an hour and a half, perhaps after a second rolling, they are finished. They are of a green colour, which subsequently brightens, the change of colour to black being prevented by the rapid roasting. Thereafter the tea is winnowed and separated into the various qualities and refired. When it is desirable to produce black tea, the leaves are allowed to lie in heaps for twelve hours or so, during which a species of fermentation occurs, which changes the natural hue of the leaf to a dark colour. Thereafter the various processes of drying, rolling, and roasting are carried out. The processes are thus described:—The leaves, after being brought in from the plantation, "are spread out upon large bamboo mats or trays, and are allowed to lie in this state for a considerable time. If they are brought in at night they lie till next morning. The leaves are next gathered up by the workmen with both hands, thrown into the air, and allowed to separate and fall down again. They are tossed about in this manner, and slightly beat or patted with the hands for a considerable space of time. At length, when they become soft and flaccid, they are thrown in heaps, and allowed to lie in this state for about an hour, or perhaps a little longer. When examined at the end of this time, they appear to have undergone a slight change in colour, are soft and moist, and emit a fragrant smell. The rolling process now commences. Several men take their stations at the rolling table and divide the leaves among them. Each takes as many as he can press with his hands, and makes them up in the form of a ball. This is rolled upon the rattan-worked table, and gently compressed, the object being to get rid of a portion of the sap and moisture, and at the same time to twist the leaves. These balls of leaves are frequently shaken out, and passed from hand to hand until they reach the head workman, who examines them carefully to see if they have taken the requisite twist. When he is satisfied of this, the leaves are removed from the rolling table, and shaken out upon flat trays, until the remaining portions have undergone the same process. In no case are they allowed to lie long in this state, and sometimes they are taken at once to the roasting-pan. The next part of the process is exactly the same as in the manipulation of green tea. The leaves are thrown into an iron pan, where they are roasted for about five minutes, and then rolled upon the rattan table. After being rolled the leaves are shaken out, thinly, on sieves, and exposed to the air out of doors. A framework for this purpose, made of bamboo, is generally seen in front of all the cottages among the tea hills. The leaves are allowed to remain in this condition for about three hours: during this time the workmen are employed in going over the sieves in rotation, turning the leaves and separating them from each other. A fine dry day, when the sun is not too bright, seems to be preferred for this part of the operation. The leaves having now lost a large portion of their moisture, and having become considerably reduced in size, are removed into the factory. They are put a second time into the roasting-pan for three or four minutes, and taken out and rolled as before. The charcoal fires are now got ready, a tubular basket, narrow at the middle and wide at both ends, is placed over the fire. A sieve is dropped into this tube, and covered with leaves, which are shaken on it to about an inch in thickness. After five or six minutes, during which time they are carefully watched, they are removed from the fire and rolled a third time. As the balls of leaves come from the hands of the rollers, they are placed in a heap until the whole have been rolled. They are again shaken on the sieves as before, and set over the fire for a little while longer. Sometimes the last operation—namely, heating and rolling—is repeated a fourth time; the leaves have now assumed a dark colour. When the whole have been gone over

in this manner, they are placed thickly in the baskets, which are again set over the charcoal fire. The workman now makes a hole with his hand through the centre of the leaves, to allow vent to any smoke or vapour which may rise from the charcoal, as well as to let up the heat, which has been greatly reduced by covering up the fires. The tea now remains over the slow charcoal fire, covered with a flat basket, until it is perfectly dry, carefully watched, however, by the workman, who every now and then stirs it up with his hands, so that the whole may be equally heated. The black colour is now fairly brought out, but afterwards improves in appearance. The after processes, such as sifting, picking, and refining, are carried on at the convenience of the workmen" (Fortune).

The quality of tea, as has been said, depends not only upon soil, cultivation, and preparation, but also upon the picking. The first crop, consisting of the young leaves, just bursting or barely expanded, and buds, is the finest. It is called Pekoe, which means white down, or Flowery Pekoe, because of the fine hairs or down clothing the leaf. Congou, Souchong, and Caper are other qualities of black tea. "Caper is in hard grains, made up of the dust of the other varieties cemented together by means of gum." Bohea is the commonest description, scarcely now found in the market. Twankay, Hyson Skin, Young Hyson, Hyson, and Gunpowder are various qualities of green tea, the Gunpowder being the finest quality, prepared from similar pickings to Pekoe. Some of the highest qualities of teas do not reach the market as such, being kept for blending. Various sweet-smelling plants are used for scenting teas, the sweet-scented olive for example, and thus there are scented Caper, orange-scented Pekoe, and so on.

The composition of tea is stated by Koenig as follows:—

Water	11·49	per cent.
Thein	1·35	,,
Essential oil	·67	,,
Tannin	12·36	,,
Nitrogenous substances	21·22	,,
Fat, colouring matter: wax, gum, dextrin	10·75	,,
Other non-nitrogenous substances	16·75	,,
Woody fibre	20·30	,,
Ash	5·11	,,

In other analyses the thein is stated as 2·0 per cent, 2·5 per cent, 3 per cent, and even more, the quantity varying with the quality of the plant, and in the same way the quantity of the essential oil varies, while the tannin, according to some, is as high as 15 per cent. It is worthy of notice that the quantities of the chief substances vary with the age of the tea leaf, the young leaves containing more water, but also more thein than the old leaves, while the latter contained more tannin and salts. It is well to contrast these quantities with those of the same constituents in coffee and cocoa, in the former of which the thein scarcely reaches 1·5 per cent, in some kinds falling as low as ·6 per cent, while the aromatic oil is only about a $\frac{3}{1000}$th per cent, and the tannin may reach only 4 per cent, while in the latter the theobromin is 1·5 per cent, and the aromatic oil is too small in quantity to be stated.

The nitrogenous substances, it might be supposed, would be of value as food; but it must be remembered that only an infusion of the leaf is commonly used, and that in boiling water the large proportion of albuminoids is insoluble, so that they are not consumed in any quantity. It has been found, for example, that half a pint of tea, made from a large tea-spoonful of the dry tea, will dissolve only about 38 grains of the material of the leaf, of which the tannin is stated at about 7½ grains, and the thein 2½ grains, while the mineral substances would be about 6 grains, leaving only 22 grains as the total of gummy, sugary, and nitrogenous substances extracted. The value of these 22 grains is, of course, not worth considering. The mineral substances consist principally of potash salts, magnesia and lime salts, phosphoric acid being also present in considerable amount.

The Value of Tea as a Food-stuff. As an example of the composition of a cup of tea, and an illustration of its valueless character as a food-stuff, that is as supplying anything for the repair of wasted tissue and yielding of energy for work or heat, I quote the following table from Attfield:—

Constituents of One Cup (seven ounces of Tea) containing average amounts of Cream (½ oz.) and Sugar (100 grains).

	Grains.
Cheesy matter from the cream	5
Fat and milk sugar ,, ,,	30
Added sugar	100
Mineral matter of the cream	1
Extract of tea leaf (mineral matter 4¾; organic 16¼)	21
Total	157

The small quantity really derived from the tea is striking; and if one takes no sugar the total amount of dissolved solids is only 57 grains, while probably half the quantity of cream

stated here is all that is usually taken. Tea, therefore, cannot be considered as yielding anything in the nature of nutriment to the body. It is simply a pleasant beverage, being used entirely for the effects due to its essential oil and active principle. The action of thein and the essential oil, given separately, has been already considered. It has been said that while tea supplies no nutriment to the body, it yet diminishes tissue waste, and thus saves the consumption of food to a slight extent, chiefly by the action of the thein. Johnston puts it thus: "The introduction into the stomach of even a minute proportion of thein—three or four grains a-day—has the remarkable effect of sensibly diminishing the absolute quantity of waste products of the tissues voided in a day by a healthy man, living on the same kind of food, and engaged in the same occupation, under the same circumstances. This fact indicates that the waste of the body is lessened by the introduction of thein into the stomach—that is, by the use of tea. And if the waste be lessened, the necessity of food to repair it will be lessened in an equal proportion. In other words by the consumption of a certain quantity of tea, the health and strength of the body will be maintained in an equal degree upon a smaller supply of ordinary food. Tea, therefore, saves food—stands to a certain extent in the place of food—while at the same time it soothes the body and enlivens the mind." I have quoted this, not because it is a reliable view of the part played by tea in the body, but because if I had stated simply the results of later experiments, some who have read Johnston's work might think I had overlooked so pronounced an opinion. For his opinion is based on a quite inadequate view of the case. Though tea diminishes tissue waste, it may nevertheless quicken the consumption of such foods as yield energy for work and heat. For if the reader will look back to p. 539 he will find that the urea cast out of the kidney is taken as a measure of tissue waste, and it is this that Johnston refers to, while the carbonic acid gas given off by the lungs is the means of estimating the consumption of fats, starches and sugars for yielding energy, and this portion of the case he has entirely overlooked. Now Dr. E. Smith, subsequent to the publication of the opinion I have quoted, made a series of experiments to determine the effect of tea on the quantity of carbonic acid given off by the lungs. He found in every case that it was markedly increased, and in his paper, published in the *Philosophical Transactions* of 1859, he states the exact figures. Now this increase implies increased consumption in the body of the energy-yielding foods, fats, starches, &c. This is quite consistent with the admitted fact that tea quickens the movement of the heart and the rapidity of the breathing, and increases the amount of heat given off from the body by the gentle stimulus to perspiration. So that even though it diminishes the waste of tissue it increases the waste of fuel, so to speak, and the result of the whole is an actual need for more food. Dr. Smith sums up the case thus: "Hence, in reference to nutrition, we may say that tea increases waste, since *it promotes the transformation of food without supplying nutriment, and increases the loss of heat without supplying fuel*, and it is therefore specially adapted to the wants of those who usually eat too much, and after a full meal, when the process of assimilation should be quickened, but is less adapted to the poor and ill-fed, and during fasting." Tea is, then, to be regarded as a stimulant, but as in no sense fitted to act as or take the place of a food. As a stimulant, however, it is a most valuable agent. Its exhilarating effect, which leaves no after depression, and entitles it to the praise of cheering without inebriating, is most useful for those engaged in intellectual work, to drive off drowsiness, and aid in removing feelings of languor and fatigue. But it is just those excellent qualities that render it most liable to abuse, when people are led by them to resort to it in states of exhaustion, when what their bodies are demanding is supplies of nourishing food, and when its stimulating properties are used to hide for the time the inadequacy of a poor or improper meal. There can be no manner of doubt that the rapid growth of tea consumption among the poorer classes, among many of whom it is found as a constituent of every meal, is doing great harm to their physical well-being. For it is supplanting far more nourishing diets, than the ordinary tea, bread and butter and bacon, &c. can ever make, and its cheering properties prevent that fact being recognized. If the meal be otherwise plentiful and nourishing, there can be no objection to a cup of tea if such is desired, and taken thus as an adjunct to the morning and evening meal it is pleasant to most people. If it is taken too frequently, however, in too large quantities or too strong, the injurious effects of thein and tannin begin to show themselves in the nervousness and tremors or in the dyspeptic stomach of the tea-drinker to excess. These bad effects are more speedily observed in those who use green teas constantly.

As a stimulant, accelerating muscular movement, and as a restorative during fatigue, tea is highly spoken of by army medical officers and generals who have commanded in the field. Parkes says of it: "As an article of diet for soldiers tea is most useful. The hot infusion, like that of coffee, is potent against both heat and cold, is most useful in great fatigue, especially in hot climates, and also has a great purifying effect on water. Tea is so light, is so easily carried, and the infusion is so readily made, that it should form the drink *par excellence* of the soldier on service." There is also a belief that it lessens the susceptibility to malaria, but the evidence on this point is imperfect.

The influence of tea on digestion has been shown on p. 603. Its slowing effect is supposed to be due to the tannin, but Roberts believes it to be due to certain acids, and to be got rid of by adding a pinch of soda.

The best way to infuse tea is to pour boiling water over the leaves in a hot cup, cover with the saucer, and allow to stand from 3 to 5 minutes. The infusion is then poured off, and no further water should be poured on in the endeavour to extract more from the leaves. "The semi-exhausted leaves are thrown away; a connoisseur never ventures on a second brew." The infusion so prepared has the delicate aroma of the plant, but wants the body and "grip" that many people think as desirable in tea as in whisky. It is a method open also to the charge of extravagance. Soft water extracts more soluble materials than hard water, and it is always proper to soften hard water with a pinch of bicarbonate of soda before using it for tea.

Adulterations of Tea.—Attfield says that owing to the vigilance of the custom-house officials adulterated tea seldom or never gains access to Britain, and is rarely, if ever adulterated afterwards; the abolition of duty has also favoured this state of affairs, though, of course, very inferior qualities are sent to market still. Formerly, however, adulteration was extensive, leaves of other plants being used, and such foreign leaves are still found. The leaves of *Camellia Sasanqua* and *Chloranthus inconspicuus* were said to be used in China, and in this country willow, sloe, oak, valonia oak, plane, beech, elm, poplar, hawthorn, elm, and horse-chestnut leaves were used, treated with gum and catechu and coloured. These could be detected by softening and spreading out the leaves on glass slides and observing the character and direction of the veins in each leaf. The border of the tea leaf is serrated, the primary veins run out from the midrib nearly to the border, and then turn in, a distinct space between them and the border being left. Exhausted leaves treated with gum and colouring matter were also used, whose presence required an analysis to show their deficiency in thein and tannin. What the Chinese called lie-tea was also largely used to adulterate. It consisted of the sweepings of the tea-houses, tea-dust, mixed with sand and often the magnetic oxide of iron, and made up into different forms with a solution of starch, to imitate various kinds of tea, especially gunpowder. A lens shows their true characters, and when some of the lie-tea is put into hot water, the binding material is loosened, and the little masses fall to pieces, showing their real nature. Tea and especially green tea was also faced or coloured, Prussian blue, mixed with gypsum, indigo, &c., were used for this purpose, the colour being added in the roasting-pan. This was done to meet the demand for a uniform and prettier colour. The actual quantity of colour would be very little, a third or fourth of a grain of the colouring matter per ounce of tea, but was still an undesirable addition. It could be detected by shaking tea up with cold water and throwing it on a piece of muslin over a glass. The colour will pass through the muslin and settle in the bottom of the glass. The water is poured off, and the colouring matter obtained. Black-lead was also used for black teas. Dr. Hill Hassall says "It will be a satisfaction to learn that the great bulk of the ordinary black teas, the Congous and Souchongs, consumed in this country, are free from admixture with foreign leaves and all other adulteration. The foreign leaves, when employed, are found principally in very low-priced and much-broken teas, and in the lower qualities of black and green gunpowder teas."

Paraguay Tea or **Maté** is prepared from the leaves of Brazilian holly (*Ilex paraguayensis*), which are dried and roasted, the whole stem and branches being cut down for the purpose. During the roasting the peculiar flavour is developed as in tea and coffee. The stems, leaves, &c., are then pounded to coarse powder in pits dug in the earth, sorted, packed in bullock-skins and set in the sun to dry. There are various qualities of it sold, according as it consists mainly of new leaves and young shoots, or leaves without twigs and stalks, or large old leaves with twigs and fragments of wood. Maté contains on an average 1·3 per cent of thein, 16 per cent of tannin, and a very small fraction of aromatic oil.

For the preparation of the infusion boiling water is poured on a tea-spoonful of the powdered leaves in a cup, a little sugar is added, and the liquid is sucked through a reed called a "bombilla." It has a narcotic action on the nervous system, and seems also to possess restorative and refreshing properties, valuable after great fatigue. It is used very extensively in Peru, Paraguay and Brazil, and people become as addicted to it as opium-eaters to their drug.

Bohemian Tea is prepared in Bohemia from the leaf of the common *Gromwell* (*Lithospermum officinale*), of the borage order of plants. It is used for adulterating ordinary tea, but contains none of the active ingredients of ordinary tea.

Coffee is prepared from the seed-beans of the coffee plant, *Caffea arabica*, of the natural order Cinchonaceæ, the same order which yields the tree from which Peruvian bark, quinine, ipecacuanha, &c., are prepared. The tree is small, shrub-like (Fig. 265), and a native of Abyssinia. It was introduced into Arabia in the fifteenth century, and the first coffee-shop was opened in London in 1652. The plant is sown in nurseries, transplanted when six months old, comes into full bearing in three years, and bears under favourable circumstances for twenty years.

Fig. 265.—Coffee Plant (*Caffea arabica*).

It is now extensively cultivated in Arabia, Ceylon, the East and West Indies, Brazil, and Central America. The fruit of the coffee tree, "which presents a superficial resemblance to a red cherry," contains two seeds, from which the pulp and covering are stripped, and which are then dried. It requires roasting for the development of the powerful volatile and aromatic oil, which gives the coffee its flavour, and which is not present, as such. previous to roasting.

The composition of Coffee is given by Church as follows:—

Water	5·0	per cent.
Thein (Caffein)	0·6	,,
Tannin	4·0	,,
Nitrogenous	15·0	,,
Gum, Colouring Matter, &c., and other extractives	34·4	,,
Fibre	36·4	,,
Saline	4·6	,,

The contrast between the amount of thein and tannin in coffee and the amount in tea has been already commented on. The aromatic oil is in so infinitesimal quantity that it has not been mentioned in the above analysis. Yet though it is in so small a quantity as to be with difficulty estimated, one part in fifty thousand, it is in this that the commercial value of the coffee depends. If the oil could be bought for the purpose of imparting the flavour, so as to add to the value of coffees of inferior aroma, it would, according to Payen, be worth £100 sterling an ounce. This oil appears to be developed by roasting to a greater extent in old than in new beans. All kinds of coffee-beans improve in their flavour by keeping, the small Mocha berries ripening in three years, but it is said that the coffee-beans with poorest flavour will, if kept for a sufficiently long time, ten to fourteen years, acquire as good a flavour as the best.

In the process of roasting, the berries swell and lose weight, 112 pounds of raw coffee being reduced to 92 pounds of roasted coffee. A chestnut-brown colour should be produced by roasting, a burnt flavour being produced when the process is overdone. Roasted coffee loses its aroma, if exposed to the air, and this it will do completely in two to four months. The coffee-drinker always prefers his coffee freshly roasted and ground. The infusion may be prepared much as tea is. Boiling drives off some of the aromatic oil, and makes the infusion deficient in flavour, while less than boiling does not extract from the ground coffee all that might be. It has, therefore, been recommended that the "grounds" from a previous infusion should be kept, that when a fresh supply of coffee is to be prepared, these "grounds" should be well boiled in water, and the hot decoction thus obtained poured over the fresh coffee, and be allowed to stand for from five to fifteen minutes, and then poured off, the "grounds" of this being retained for the next infusion. Thus both body and flavour would be secured. Coffee yields more extractives to soft than to hard water; to the latter a pinch of bicarbonate of soda should be added.

Constituents of a Breakfast-cupful of Coffee with ¾ oz. of Cream and ¼ oz. Sugar.

	Grains.
Cheesy matter from the cream	7½
Fat with sugar from milk and from seed	41
Added sugar	140
Extract from coffee seed (mineral 11; organic 41)	52
Mineral matter in cream	1½
Total	242

The action of coffee upon the body is similar to that of tea. It does not supply any nutriment worth considering, as the table showing the constituents of a cup of coffee indicates. Containing as it does less thein, more can be consumed than of tea, and the marked decrease in the amount of tannin renders it less liable to interfere with digestion. It was supposed that coffee diminished tissue change, as had also been alleged of tea. This has been shown to be inaccurate. It acts as a stimulant upon the nervous system, and upon the heart, and it increases the rate of breathing, and the amount of carbonic acid expelled. It acts also upon the kidneys, increasing the amount of water expelled by these organs. It tends also to produce a relaxing effect upon the bowels, while the effect of tea is rather binding. The active principle, thein or caffein, is an excellent remedy for nervous headache, given in from 1 to 3 grain doses. In excessive doses coffee acts injuriously upon the nervous system as does tea, producing brain excitement, nervous tremors, and wakefulness.

Coffee is especially useful during fatigue, as it invigorates without producing depression later; and it has marked power in relieving the feeling of hunger. It readily induces indigestion in the case of the dyspeptic, but not so readily as tea. Its stimulating effects are very useful in opium-poisoning, in nervous headache, and in other conditions. It often relieves the spasm of asthma.

Chicory is commonly added to coffee to give it increased "body." This is the root of the wild succory or wild endive (*Cichorium Intybus*), belonging to the natural order Compositæ, as do the dandelion and lettuce. It is extensively cultivated in Germany, Holland, and Belgium for this purpose. It grows wild in Britain, by the roadside, blossoming with pale-blue flowers in August and September, the stem rising from 1 to 3 feet in height. It has a long taproot like parsnip, white and fleshy, containing a milky bitter juice. The root is used before the blossoms are due, being cut into pieces, kiln-dried, roasted in revolving iron cylinders, with lard to the extent of 2 lbs. for every hundredweight of the dried root, and ground. Thus prepared it markedly resembles coffee, and contains a volatile oil giving aroma, but not of the character of the volatile oil of coffee, and it contains some bitter material, but no such tannic acid as is found in coffee and no caffein. It gives increased colour to coffee and strengthens the flavour, and its addition is desired by many people. In Germany it is much used, as much as 5 lbs. per head of the population being consumed in Belgium. It is not unwholesome, if used in small quantities, but it appears to act upon the bowels, tending to produce diarrhœa, and is apt to cause pain in the stomach, flatulence, &c. The presence of chicory in coffee can be detected by pouring some of the coffee on *cold* water in a wine-glass. Coffee floats for a long time, whereas chicory sinks at once. Moreover, coffee does not colour cold water, and chicory does.

Chicory is itself adulterated, roasted corn, wheat, beans, acorns, mangold-wurzel, dandelion-root, and various red earths being used for this purpose.

Coffee leaves have long been used in the Eastern Archipelago to yield a kind of tea. The leaves are roasted over a clear fire, then separated from the twigs, from which, after a second roasting, the bark is removed and mixed with the leaves. They make a clear brown infusion, which is drunk with cream and sugar like tea, and have a fragrant odour resembling a mixture of tea and coffee. In Sumatra this forms "the only beverage of the whole population," being preferred to the infusion of the berry. The leaves contain 1½ per cent of thein, as well as a volatile oil, and some astringent substance. According to Dr. E. Smith, the infusion does not excite either the pulse or breathing, but decreases both; and he accordingly thinks there is no probability of them supplanting either tea or coffee in the duty they perform in the human body.

Cocoa (Fig. 266) is the seed of a tree, the *Theobroma Cacao*, native to Mexico, West Indies, and South America, and it is chiefly grown in Brazil, Guiana, and Trinidad. Forests of it are grown in Demerara; it belongs to the natural order Byttneriaceæ. The fruit of the tree is of the shape of a small cucumber, and contains a sweetish pulp, in which 50 to 100 seeds are imbedded, arranged in rows, with partitions between them. The ripe fruit is collected in heaps on the ground or in earthen vessels, during which it undergoes a fermentive change, which develops an aromatic smell, and becomes soft. The seeds are then removed, cleaned, and dried in the sun. They are dark-brown in colour, and almond shaped. For use they are roasted in

Fig. 266.—Cocoa (*Theobroma Cacao*).

iron cylinders, which develops the aroma. Deprived of the husks and simply crushed, they form **cocoa-nibs**, the purest kind of cocoa obtainable. The bean, after roasting, is also crushed under hot rollers, mixed with sugar and flavouring materials, and formed into a paste, called **chocolate**. Or the ground cocoa is mixed with sugar, starch, or other ingredients, and sold as soluble cocoa, rock cocoa and flake cocoa being produced in a similar way. In the inferior cocoas there is some of the husk, ground down as finely as possible and added to the ground bean.

The composition of cocoa shows some very important differences from that of tea and coffee.

Water	6·0
Theobromin	1·5
Fat (Cocoa Butter)	50·0
Starch	10·0
Albuminous	18·0
Gum	8·0
Colouring Matter	2·6
Fibre, &c.	0·3
Saline	3·6

Of the above constituents the most notable are the theobromin and fat. The former has been already noticed, in considering thein, &c. (p. 654). There is no statement of aromatic oil or tannin, the quantities of these substances being excessively minute. The remarkable feature is the large quantity of fat, cocoa-butter, or oil of theobromin. It is about the consistency of tallow, yellowish-white, with the marked odour of chocolate, and a pleasant taste. It keeps for any length of time, when pure, always retaining its agreeable odour, and on this account it is used by druggists as a basis for suppositories.

Value of Cocoa.—The fat, as well as the albuminous, gummy and starchy constituents, make cocoa highly valuable as a food-stuff. For it is to be remembered that the preparation of cocoa for use is of a different kind from tea or coffee. If an infusion only were used, as is the case with the latter, these constituents would be of as little importance as the albuminoids of tea and coffee. But it is not an infusion that is employed, but a simple mixture with water, so that the whole of the ground cocoa is introduced into the body. This is a point of very great importance. When it is duly considered it is evident that cocoa possesses a very high value as a food-stuff. Reference to the table shows that no less than 86 per cent is of value for the repair of tissue or the liberation of energy, the high value of fat for the latter being borne in mind. About 14 ounces of each pound consists of useful material. It is indeed a food rather than a beverage; but, at the same time, the theobromin and minute quantity of aromatic oil give it qualities of a stimulating, fatigue-removing, and invigorating character, similar in character to, though not so pronounced in amount as, those of tea and coffee. It is to be noticed, however, that the nibs are used in a way to produce rather an infusion with properties like tea or coffee. They are gently boiled in water for a couple of hours, the liquid portion is then poured off, and the undissolved parts of the nibs thrown out. This method of preparation dissolves only part of the seed, and the beverage produced falls far short, in nutritive qualities, of the material made by mixing the cocoa ground to a fine powder with boiling water.

There is now in the market a very large number of prepared ground cocoas, of exceedingly delicate flavour and of great nutritive value—Van Houten's, Tulloch's Pure Dutch Cocoa, Fry's Pure Cocoa, and so on. It would be the greatest possible benefit to many if they would substitute cocoa for tea or coffee at least once a day.

The quantity of fat present in cocoa makes it feel rather heavy and somewhat difficult of digestion to many. Hence the manufacturers of prepared cocoa endeavour to reduce the quantity of fat, either simply by abstracting some of it and leaving the cocoa otherwise unaltered, which is the preferable way, or by diluting the cocoa with sugar, or starch, or other similar substance, various kinds of sugar and starches being employed for the purpose. In some of the cocoas in the market it is said there is not more than 30 per cent of pure cocoa, the rest being additions of sugar, starch, &c., with colouring matter. Such additions are, properly speaking, adulterations. To such prepared or diluted cocoas, where the dilution is acknowledged and its extent duly stated on the label, there is no serious objection, but they ought not to be sold under the name of pure cocoa, homeopathic cocoa, dietetic cocoa, or the like.

The adulteration of cocoa with arrow-root, potato starch, and other starches, can readily be detected by means of the microscope (see p. 598).

It may be remarked that if cocoa is diluted with sugar simply, the cocoa needs only the addition of boiling water; but if it has been diluted with starch, the simple addition of boiling water will not properly cook the starch, will not render it soluble, and such cocoa would be rendered more digestible by boiling for a few minutes.

The saline matters of cocoa consist chiefly of potash salts and phosphates.

Brazilian Cocoa, or **Guarana,** is derived from the seeds of a small climbing plant (*Paullinia sorbilis*) growing in Brazil, belonging to the natural order *Sapindaceæ,* or soap-worts. The seeds are dried, then roasted, powdered, and made into a stiff paste with water, being mixed with some of the whole and broken seeds, and pressed into cylindrical masses, not unlike sausages, and called **guarana-bread.** Pieces are broken from the rolls and infused in hot water, like tea or coffee, to form a beverage, which is sweetened, and is said to be as grateful and refreshing as either of the latter. The active principle of gaurana is called *guaranine,* but is identical with thein, and exists to the extent of five per cent in the guarana rolls, which also contain tannin, gum, &c. In short, the beverage presents marked resemblances in its active constituents and in its effects to both tea and coffee, being used as a nerve stimulant and restorative. Powdered guarana, as well as the active principle, are used in medicine as a nerve tonic, and the former, because of its astringent property, is employed for diarrhœa and dysentery. Powdered guarana in 30-grain doses is most valuable for sick headache (see p. 113). It is extensively used in Brazil, Costa Rica, and other parts of South America.

Coca, or **Cuca,** is not to be confounded with cocoa. Coca leaves are derived from a shrub found growing on the mountains of Bolivia and Peru, called *Erythroxylon coca.* The leaves are used very extensively by the natives, and in South America it is said the annual consumption of leaves cannot fall short of 100,000,000 pounds. The late Sir Robert Christison, of Edinburgh, was the first in this country to investigate the action of the drug, and the following gives some interesting detail of his experiments on himself:—"In the beginning of May, under a day temperature of 58°, I walked fifteen miles in four stages, with intervals of half an hour, at four-mile pace, without food or drink, after breakfast at half-past eight, and ending with a stage of six miles at half-past five in the afternoon. I had great difficulty in maintaining my pace through weariness towards the close, and was as effectually tired out as I remember ever to have been in my life, even after thirty miles at a stretch, forty or fifty years before. . . . The pulse, naturally 62 at rest, was 110 on my arrival at home, and two hours later it was still 90. I was unfit for mental work in the evening, but slept soundly all night, and awoke next morning somewhat wearied and disinclined for active exercise, although otherwise quite well. Two days afterwards I repeated this experiment, and obtained precisely the same results. . . . Four days later, with precisely the same dietary, I walked sixteen miles in three stages of four, six, and six miles, with one interval of half an hour and a second of an hour and a half. During the last forty-five minutes of the second rest I chewed thoroughly eighty grains of my best specimen of cuca, reserving forty grains more for use during the last stage. To make assurance doubly sure, I swallowed the exhausted fibre, which was my only difficulty. On completing the previous ten miles, I was fagged enough to look forward to the remaining six miles with considerable reluctance. I did not observe any sensible effect from the cuca till I got out of doors and put on my usual pace, when at once I was surprised to find that all sense of weariness had entirely fled, and that I could proceed not only with ease, but even with elasticity. I got over the six miles in an hour and a half without difficulty, found it easy when done to get up a four-and-a-half-mile pace, and to ascend quickly two steps at a time to my dressing-room, two floors up stairs; in short, had no sense of fatigue or other uneasiness whatsoever. On arrival at home the pulse was 90, and in two hours had fallen to 72. . . . Before dinner I felt neither hunger nor thirst, after complete abstinence from food and drink of every kind for nine hours; but on dinner appearing in half an hour, ample justice was done to it. Throughout the evening I was alert, and free from all drowsiness. Two hours of restlessness on going to bed I ascribed to the dose of two drachms being rather large; and after that I slept soundly, and awoke in the morning quite refreshed and free from all sense of fatigue and from all other uneasiness."

It is right to say, however, that every experimenter has not obtained such satisfactory results as Sir Robert Christison, though there is some reason for believing that failure is due to fresh leaves not being used, as there seems no doubt coca spoils with keeping.

Coca appears then to act somewhat like tea and coffee, stimulating the nervous system and lessening fatigue, for which purpose it is used by the Indians in Peru on long marches.

Coca yields an alkaloid, *cocaine,* which has the remarkable property of abolishing the sensibility of the skin and mucous membrane. Thus when a solution is applied to the tongue or throat, sensation is abolished in a few minutes,

taste being in abeyance for some time. A couple of drops instilled into the eye will in a few minutes destroy sensation there, so that an operation may be conducted without pain. Sensation returns again after the lapse of some hours.

Kola-nut is the fruit of a tree, *Sterculia acuminata*, indigenous to Central Africa. The roasted nut is used to yield an infusion, employed by the inhabitants of Central Africa much as tea and coffee are. It contains fully 2·3 per cent of caffein, also 0·023 per cent of theobromin, and fully 1·6 per cent of tannin. An extract called *kolatina*, to be used like cocoa, is now to be had, and is said to be a stimulating beverage, having no bad effects upon the digestion.

ALCOHOLIC DRINKS.

Alcoholic drinks embrace a great variety of beverages, ardent spirits, wines, malt liquors, and so on. These all possess in common the one great feature of containing in greater or smaller quantity the spirit of wine or alcohol; and it will be well if we first of all consider what alcohol is, how it is obtained, and what are its effects upon the body. This will afford a basis for considering the characters and effects of the various liquors in which it forms an ingredient.

Alcohols.

Composition of Alcohol.—Alcohol is a word derived from Arabic, and implies anything very subtle. It was a term originally applied only to the spirit distilled from wine, and meant simply the spirit of wine. Chemists investigated its chemical character, and found it to be a definite compound of carbon hydrogen and oxygen, in certain proportions, namely, two combining weights of carbon, six of hydrogen, and one of oxygen; and thus alcohol was represented by the chemical formula C_2H_6O, expressive of the elements entering into the composition of alcohol, and the proportions in which they combined. It was then found that there was a series of substances, related to this spirit of wine from a chemical point of view, formed of the same elements in other proportions, and this series of substances came to be classed together as alcohols. The most commonly known of these substances are:—

Methylic alcohol or wood spirit or wood naphtha (CH_4O).
Ethylic alcohol or spirit of wine (C_2H_6O).
Amylic alcohol or potato spirit or fousel-oil ($C_5H_{12}O$).

Methylic alcohol is obtained by the destructive distillation of wood. Methylated spirit is ordinary alcohol, spirit of wine, to which this wood spirit is added, to prevent it being used for drinking purposes, and thus permit it being used for commercial purposes at a cheap rate. Amylic alcohol or potato spirit is usually produced in the processes of fermentation by which ordinary alcohol is obtained. It is the presence of this potato spirit in whisky which gives its peaty smell and burning taste. There is a large number of other alcohols, propylic, butylic, caproic, caprylic alcohols, and so on, many of which are produced in the fermentation of sugar along with ordinary alcohol, giving peculiar characters to the fermented liquor. It is, however, with ethylic alcohol, or spirit of wine, which is the one commonly meant when one speaks of alcohol, it is with it we have to do.

Preparation of Alcohol.—The ordinary alcohol with which everyone is familiar is produced in solutions containing sugar by a process of fermentation. This process is due to the activity in the solution of a little organism, the yeast plant. It is a single cell (Fig. 267), round

Fig. 267.—Yeast Cells (ferment) growing during forty-eight hours: (*a*) magnified 200, and (*b*) 400 diameters. After Beale.

or oval, measuring in its greatest diameter on an average about $\frac{1}{3000}$th of an inch, some larger and some smaller. Each little cell is an independent organism, capable of living and, unaided, reproducing its kind. This latter it accomplishes by budding. A minute prominence appears at some part of the surface of the cell, enlarges, and finally attains a size nearly equal to that of the mother cell. The connection between the two becomes narrowed, and finally the young cell separates and becomes an independent organism, speedily throwing off buds itself. The cells thus multiply in a suitable medium with enormous rapidity. Let any one who owns a microscope take a minute speck of brewer's yeast on a glass slide, place on it a drop of water, mix the two, cover with a cover-glass, and examine under a lens magnifying by 300 diameters, and he will see hundreds of such bodies as are depicted in Fig. 267. Now when such yeast is sown in a sugary solution, let us say in the juice expressed from ripe grapes, it proceeds to multiply with great rapidity. It does so at the expense of the

solution, and as an absolutely necessary part of its vital operations, it produces chemical changes in the sugary solution. The sugar, which consists of carbon, hydrogen, and oxygen, is split up into two different substances, part of the carbon going with part of the oxygen to form carbonic acid gas (CO_2), and the remainder of the carbon going with hydrogen and oxygen to form alcohol (C_2H_6O). Sugar disappears, that is to say, and alcohol and carbonic acid gas take its place, produced from it by the activity of the yeast plant. Thus it is that if anyone sows yeast in a sugary solution and keeps it at a moderate temperature, minute bubbles of gas will be seen rising in great numbers, bubbles of the carbonic acid gas escaping, and alcohol will have been produced in the solution. Very many most elaborate researches have been made by the most distinguished chemists, such as Lavoisier, Gay-Lussac, Thénard, De Saussure, and Pasteur, to determine whether the quantity of carbon, hydrogen, and oxygen in the sugar which disappeared could be accounted for in the quantity of alcohol and carbonic acid gas produced, with the result of obtaining almost exact correspondence. Thus 105·26 parts of grape-sugar (equal to 100 parts of cane-sugar) have been found to yield:—

Alcohol	51·11 parts.
Carbonic Acid Gas	48·89 „

which, along with 5·26 parts of other substances formed in course of the fermentation, such as glycerine, succinic acid, and a small proportion united with the yeast, make up the 105·26 parts of grape-sugar.

Alcohol then is produced by the agency of a living organism from the decomposition of sugar. One pound of sugar yields rather over ½ lb. of proof spirit, or over ¼ lb. absolute alcohol. It is only, however, from sugars capable of fermentation that alcohol is produced *directly*. Such sugars are grape-sugar, in particular, found in many vegetable juices, muscle-sugar or inosite and other similar sugars, already noted on p. 587. Cane-sugar, beetroot-sugar, and milk-sugar are not capable of immediate fermentation, but can be converted into grape-sugar by various means and then made to yield spirit. Moreover, we have seen that starch is capable of conversion into sugar by the agency of various ferments, and is so converted in the body by the action of saliva (p. 143) and pancreatic juice (p. 145) as a necessary part of the process of digestion. Further, we have noted that the starch so richly present in wheat may be converted into sugar by the action of a ferment, present in the wheat grain itself (p. 559), that the starch of the barley grain is also convertible into sugar by a ferment present in the barley, produced in the grain in the process of germination, and that it is only necessary to place the grain in circumstances of heat and moisture for that process of conversion to proceed. Hence it follows that when such conversion is achieved it is only needful further to add some yeast, to set agoing the second process by which alcohol will be produced. Starch may be converted into sugar by chemical means, by boiling with sulphuric acid, and it is grape-sugar that is thus formed. It is evident, therefore, that any substance whatever which contains either sugar or starch can by the appropriate means be made to yield alcohol. So not only fruits like grapes, and vegetables like turnips and potatoes, but an infinite variety of incongruous substances, old paper, dusty legal parchments, raw cotton and flax, rags, and even sawdust can be made to yield alcohol. The quantity of starch or sugar in these latter substances is, however, too small to permit of alcohol being manufactured from them except at great cost. Hence in the production of alcohol the cereals which contain starch in large quantity, barley, &c., are commonly used. Potatoes, also rich in starch, are largely used on the continent of Europe to yield an inferior spirit—potato brandy. 100 lbs. of corn yield nearly 3½ gallons proof spirit, and one bushel of malted barley produces, on an average, 2 gallons of spirit; while 100 lbs. of starch yields 70 lbs. sugar, and that yields 8 gallons proof spirit.

Though it was known in very early times that vegetable juices like that of the grape, if allowed to ferment, underwent some change by which an intoxicating character was produced, the real substance—the spirit—to which this was due was not known by itself, and was not separated from the wine till the twelfth century, when Abucasis, by a process of distillation, was able to separate it. Hence the name, spirit of wine, given to it.

The method of producing whisky will illustrate the various processes in the preparation of alcohol. For the manufacture of whisky barley is employed. It contains (p. 558) fully 65½ per cent of starch. The whisky manufacturer has therefore three processes to conduct: (1) he must get the starch converted into grape-sugar, and obtain this in solution, (2) he must excite in the sugary solution the alcoholic fermentation, and cause it to be maintained till all the sugar

is converted into alcohol and carbonic acid gas, (3) he must then separate out the produced spirit. The first process is called **malting the grain**, and the solution obtained is called the **wort**, the second process is the **fermentation of the wort**, and the third process is that of **distillation.** The barley is first steeped in water till the grains are well swollen. After being drained it is spread out on the floors of the malt-house, when germination begins and much heat is developed. The germination is allowed to proceed till the germ (acrospire) is about to burst the seed coat, which occurs in from fourteen to twenty-one days. At this stage further sprouting is stopped by the grain being dried in a kiln. The changed grain is now called malt, and is of a pale, amber, or dark colour according to the heat applied in drying. Malt differs from barley in containing a small proportion of sugar, and specially in containing a ferment, called **diastase,** which did not previously exist in the barley grain, but is produced in the course of germination. Now this diastase possesses the property of converting starch into grape-sugar with great rapidity. Accordingly the next business of the whisky manufacturer is to place the malt in such circumstances that the diastase will have free opportunity of performing its task. Accordingly the malt is bruised and placed in a large vessel called a mash-tun, water at a temperature of from 157° to 160° Fahr. being mixed with it. The water dissolves the sugar already present in the malt, as well as the diastase, which thus gets ready access to the starch of the malt, and the conversion into sugar proceeds with great rapidity. In a few hours it will be complete. So active is diastase that 1 part can convert 200,000 of starch. "Thus 100 parts of starch made into a paste with 39 times its weight of water, and mixed with 6·13 parts of diastase in 40 parts of water, produced 86·9 parts of sugar in one hour" (Smith). The activity of the ferment is so great that it is capable of converting a much larger quantity of starch into sugar than is actually present in the grain. On this account it is common to add to the mash-tun unmalted grain, or starch derived from other sources such as potatoes. By this means the trouble of malting a considerable amount of grain is saved, as well as an actual loss of substance; for in the malting process there is a loss of solid matter of the barley to the extent of thirteen per cent. Whisky thus produced has, however, a harsher and less agreeable flavour than that entirely obtained from malted grain, and is an inferior article. When the starch has all been converted into sugar, the sweet wort, as the infusion is called, is boiled to destroy the diastase. The boiled liquor is then run off, cooled, and transferred to the fermenting tun, where yeast is added, and allowed to act till all the sugar has been split up into alcohol and carbonic acid gas. In the final process the fermented liquor is placed in a vessel called a still, set over a fire. From the dome-shaped cover of the still passes a tube, which proceeds in a spiral fashion, and is hence called a worm, through a vessel which contains cold water. The heat raises the alcohol as vapour, and in passing through the worm, it is condensed and caught in the receiver. The alcohol passes over along with a considerable quantity of watery vapour, and pure alcohol is not immediately obtained. What is obtained by the first distillation may be again distilled, and again and again, but even when repeatedly redistilled, the spirit still contains about 9 per cent of water, which can only be got rid off by other means. Moreover, not only water passes over with the alcohol, but also the vapour of other substances produced in the wort. The nature of these other substances depends upon the source of the spirit, grape-juice, barley, rye, &c., and it is their presence which gives to the spirit its peculiar character and flavour. Thus acetic acid and fousel-oil are usually present in small quantities.

Rectified Spirit is spirit from which all impurities, such as fousel-oil and acetic acid, have been removed by redistillation and other means. But, as already said, the most highly rectified spirit still contains 9 per cent of water.

Absolute Alcohol is the term applied to perfectly pure alcohol, from which all the water as well as other impurities have been removed. It is transparent and quite colourless; "has an enlivening odour and a burning taste." It is lighter than water. At a temperature of 68° Fahr., a vessel which will hold 1000 grains of water will, if filled with absolute alcohol, weigh 208 grains less, that is its specific gravity is only 792, that of water being taken as 1000.

Proof Spirit is the proportion of spirit and water allowed by act of parliament for excise purposes. It is said to consist of:—

Alcohol (by weight)	49·24
Water (by weight)	50·76

in 100 parts (by weight) of proof spirit. Spirits weaker than this are said to be under proof, and stronger than this are said to be over proof.

Fifty over proof means that the strength of the spirit is such that to every 100 parts of the spirit 50 parts of water would require to be added to reduce the strength to proof; or if the spirits be 20 over proof, 20 parts of water need to be added to every 100 parts of the spirits to bring them down to proof. On the other hand 30 under proof would mean that every 100 parts of the spirits contained only 70 parts proof spirit and 30 of water.

Proportion of alcohol in various spirits, wines, &c.—The proportion of pure alcohol by volume in the various spirits, wines, &c. in common use is shown in the following table:—

Brandy	55·39 per cent.
Whisky (Scotch)	54·32 ,,
Whisky (Irish)	53·20 ,,
Rum	53·68 ,,
Gin	51·60 ,,
Port Wine	20·25 ,,
Sherry Wine	16·30 ,,
Madeira Wine	16·10 ,,
Claret and Hock	8 to 13 ,,
Champagne	7 to 12 ,,
Edinburgh Ale	5 to 6 ,,
Porter	5 to 7 ,,
Lager Beer	5·1 ,,
Cider (average)	6·0 ,,
Gooseberry Wine	3·0 ,,
Ginger Wine	1 to 6 ,,

Brandy is prepared by distilling wine, or at least ought to be so prepared; 1000 gallons of wine yield from 100 to 150 gallons of brandy, containing from 50 to 54 per cent of absolute alcohol. Its quality varies with the wine from which it is prepared. The most delicate is yielded by white wine, and the white wines of the Cognac and Armagnac districts of France are specially prized for the purpose. Inferior wines are used to obtain cheaper qualities of brandy; poor qualities are produced from the refuse of grapes, wine-presses and wine casks, being made up with other substances. Much alcohol sold as brandy is simply spirit obtained by the fermentation of sugar, as in the preparation of whisky, coloured with burnt sugar and flavoured. Thus the fiery spirit produced in Germany from potato starch is, after redistillation in France and colouring, sent over to Britain as brandy. Brandy when produced is colourless, and obtains its dark hue from keeping in oak casks. "The brandy made in England is for the most part artificial. A very usual process is to add to every 100 parts of proof spirit from half a pound to a pound of argol [the tartar from the inside of wine casks] some bruised French plums, and a quart of good Cognac; the mixture is then distilled, and a little acetic ether, tannin and burnt sugar added afterwards" (Blyth).

The peculiar flavour of brandy is derived from the wine from which it is distilled, and depends on various volatile oils and œnanthic ethers, which pass over with the spirit in course of distillation. Some of these are also produced by slow chemical changes of the nature of oxidation, changes which go on in the brandy if it is kept long, and which also vary with the original quality of the spirit. Thus brandy contains besides alcohol and water, acetic, œnanthic, butyric, and valerianic ethers, small quantities of grape-sugar, minute quantities of a volatile oil, colouring matter, a trace of tannin, acetic acid, and a little fixed acid. Old brandy is characterized by the presence of these various ethers, to which the special flavour is due.

Whisky.—Whisky is prepared from malted barley, or often a mixture of malted barley and raw grain as is common in Ireland. It also contains various volatile oils which pass over in distillation. It also is improved by age, harshness and fieriness being mellowed thereby. The peaty flavour is said to be due to the peat or turf fires over which the malt is dried. But one ingredient, almost commonly present, confers a peaty taste, namely fousel-oil or potato spirit. A small quantity is produced in course of manufacture, but it is sometimes added as an adulteration, being cheaply prepared. It is this which gives the fiery taste to crude spirits; and it is an injurious ingredient, producing headache and giddiness, from which men engaged in the production of potato spirit suffer, unless some arrangement exists for preventing inhalation of the fumes. Whisky is by preference kept in sherry casks to acquire colour and flavour. Whisky also contains some acetic acid, but should contain no sugar.

Rum is the spirit distilled from molasses which have been allowed to ferment. It is coloured with caramel. It is a West Indian product, where molasses, skimmings from sugar-boilers, &c. are mixed with water and distilled after fermentation. Poor qualities are prepared from the waste of sugar-cane. In France it is also manufactured from the skimmings, &c. of the beet-sugar factories. The finest qualities are rich in volatile and essential oils, and by keeping it acquires a very soft mellow flavour. It may also contain a small quantity of sugar and acid. To every 6 cwt. of sugar produced on a plantation there is usually also 1 gallon of rum.

Rum which, by age, has lost in alcoholic strength and gained in flavour by the development of œnanthic ether is, according to Dr. Ed. Smith, the purest and most healthful member of the spirit class, and the most perfect cordial with which we are acquainted.

Gin is entirely a prepared spirit, made up usually of an inferior alcohol, distilled from barley malt and unmalted rye, and apt to contain a considerable proportion of fousel-oil, and flavoured by means of various substances, specially juniper berries, coriander seeds, orris root, angelica root, grains of paradise, cardamom seeds, cassia buds, turpentine, creasote, &c. The name gin is derived from Genièvre, French for the juniper, and this supplied the term Geneva by which it is sometimes called, which became corrupted to gin. It was at first imported from Holland only, and thus went under the name "hollands." "Cordial gin," or "Old Tom," is the same article sweetened. The juniper berries give it diuretic properties, that is cause it to act upon the kidneys, so as to increase the quantity of water passed. After the spirit has been distilled over from the fermented grain, it is submitted to a redistillation for the purpose of rectifying it. It is at this stage the juniper berries and other materials are added, the redistillation then proceeding. Each distiller usually has a mixture of flavouring ingredients of his own liking.

Arrack is the distilled spirit of the fermented juice of the cocoa-nut tree, and is obtained also from palm-wine (see p. 581). It is also distilled from fermented rice liquor. It contains usually 52·7 per cent of alcohol, and it is largely consumed by the Hindoos and Malays.

Liqueurs or **Cordials** are strong spirits, usually highly sweetened, and flavoured by various fruity or aromatic substances. They are also commonly brightly coloured by means of cochineal, turmeric, &c. They are used to stimulate digestion, and are taken in small quantities at the end of dinner.

Absinthe is flavoured with the oil of wormwood (*Artemisia Absinthium*), and with peppermint, angelica, cloves, cinnamon, and aniseed. It is coloured green by vegetable juices. It contains 50 per cent of alcohol, and 1½ of sugar. The oil of wormwood is present to the extent of ⅓rd per cent. The oil of wormwood has a poisonous action on the nervous system, and absinthe is said to be "one of the most treacherous and pernicious for habitual use of all the liquids of the alcoholic class" (Pavy).

Curaçoa is a liquor containing 47 per cent alcohol, 28½ per cent cane-sugar, and is flavoured with orange peel.

Benedictine has 44 per cent alcohol and 32½ of cane-sugar.

Noyeau is flavoured with the kernels of peach, apricot, bitter almonds or cherry. It is cherries which flavour **Maraschino** and **Kirschwasser.** The latter is distilled from the fermented juice of bruised cherries, in which the kernels of the stones have been kept. **Chartreuse** has a flavouring of angelica oil and a peculiar kind of turpentine.

The Effects of Alcohol on the Body and Its Value.—Is Alcohol a Food? On the answer to this question largely depends the estimate one will form of the value of alcoholic drinks to the body. What the meaning of that question is, no one, who has read the early pages of this section with any understanding, ought to have any difficulty in apprehending. Does it yield up anything to the body for the repair of tear and wear of tissue? or does it undergo combustion in the body to yield energy for heat and work? These are the two parts of the same question. It consists of carbon hydrogen and oxygen only, and the absence of nitrogen at once settles the question of its power to aid directly in the repair of wasted tissue, but its carbon and hydrogen are capable of combustion. From such chemical considerations Liebig came to the conclusion that it was a respiratory food, that its carbon and hydrogen underwent combustion to carbonic acid gas and water, yielding energy for heat. "Of all respiratory matters," he says, "alcohol acts most rapidly." . . . "Alcohol stands high as a respiratory material. Its use enables us to dispense with the starch and sugar of our food, and is irreconcilable with that of fat." Later than this, researches undertaken by certain French investigators, Lallemand, Duroy, and Perrin, went to show that Liebig had been mistaken. Their experiments seemed to show that alcohol, taken into the body, passed through it *unchanged;* and their conclusions were based upon the fact that shortly after alcohol had been taken, it could be detected escaping by the breath, the urine, and the skin; and could be so detected for many hours. They therefore concluded that it was all given off from the body as alcohol. If this were so, it is obvious it could not be considered a food, for it could not undergo oxidation for the liberation of energy for either heat or work. They therefore stated that it was not in any sense a food. These results were confirmed by Dr. Edward Smith, who detected alcohol in the

breath four hours after $1\frac{1}{2}$ oz. had been taken. It was shown, however, by Dr. Anstie (1864), and in the preceding year by M. Baudot, that although it was quite true that alcohol can be detected as such in the breath, sweat, and urine for many hours after alcohol has been taken in any quantity, yet the quantity so cast off from the body is only a very small fraction of what has been consumed. Dr. Anstie showed that the tests employed were extremely delicate, and would indicate the presence of alcohol, even though only a very minute quantity escaped from the body unaltered. These results were corroborated in 1872 by Dr. A. Dupré, who found that only a minute fraction of the amount of alcohol taken was cast off as such in the breath, sweat, &c., and that the greater portion was retained and destroyed in the body. What changes it undergoes is not known, but it is thought to be a reasonable conclusion that it undergoes oxidation, and sooner or later is used for the liberation of energy as work or heat. Dr. Parkes, however, inclines to the view that it becomes changed simply to acetic acid, and that it might subsequently unite with the soda of the blood, finally being expelled in the urine in the form of a carbonate. "If this view is correct," he says, "the use of alcohol in nutrition would be limited to the effects it produces, first as alcohol, and subsequently as acetic acid, when it neutralizes soda, and is then changed into carbonate."

On the whole the present generally accepted view is that alcohol does take rank as a food, undergoing changes in the body leading to the liberation of energy. There is also some more or less valuable evidence that alcohol can replace food to some extent, that if the food is insufficient for the bodily wants, the addition of a small quantity of alcohol will remedy the deficiency. Thus Dr. Anstie relates a number of very remarkable cases, not of persons suffering from disease only, but also of persons otherwise healthy, who regularly took an amount of food utterly insufficient for bodily purposes, and along with it a considerable supply of alcohol, and who did not exhibit any of the signs of emaciation and prostration that would be expected, in whom, that is to say, alcohol took the place of food. These cases, however, are so remarkable that Dr. Anstie hardly offers sufficient proof of their entire credibility. Dr. Hammond, however, an American physiologist, made a direct experiment of this kind upon himself. He took for sometime an insufficient diet, and found he was daily losing weight upon it. He then added to it only a small proportion of alcohol and, thereupon, found that he not only ceased to lose weight, but actually converted the loss into a gain. For such reasons the conclusion indicated has been arrived at, that alcohol is able to a certain extent to take the place of a certain amount of the necessary daily quantity of food.

There is another way in which it appears alcohol may affect the nutrition of the body. It appears certain that alcohol diminishes oxidation changes going on in the body. It diminishes combustion, the consumption of material going on in the body. This is effected by lessening the rate at which the blood gives up oxygen to the tissues, and as oxidation cannot go on in the body without the proper supply of oxygen any more than a fire can burn without a proper supply of air (see p. 527), so this lessening of the amount of oxygen to the tissues diminishes the tissue waste. Such a diminution of combustion is not a desirable thing in a state of health. It implies an interference with the natural processes of the bodily economy, and a lessened liberation of energy for work. It may be, and very often is, a most desirable result to obtain in a state of disease; but it is scarcely correct to call alcohol a food because of this effect. It is, on this account, rather a drug, such as quinine which exerts a similar influence. It is probable that the fattening effect of alcohol, the tendency to an unhealthy deposition of fat in persons who drink considerable quantities of alcoholic liquors, is due to this result of diminished oxidation. In particular this is noticeable in those who drink largely of malt liquors, in which there is present sugar to a greater or less extent. The consumption of this, as well as of sugars and fats in the food, being prevented, it is converted into fat and deposited. Moreover it is a well-known tendency of alcohol, when used to excess, to produce fatty degeneration of various organs of the body.

Setting aside, however, this fact of the diminished oxidation due to alcohol, as being, on the whole, prejudicial in a state of health, however useful in disease, and as not justifying the description of alcohol as a food, and accepting the view that it can besides undergo combustion in the body to yield energy, and, on this account, to be rightly reckoned to some extent as a food-stuff, the question that next arises is to what extent does alcohol become useful, in a state of health, in virtue of its latter property? Supposing it to be admitted to the class of energy-yielding foods, may it be employed to

any extent as such? Supposing enough of albuminous foods, such as beef, eggs, fish, &c., be given to supply waste of tissue, could alcohol be given in sufficient quantity to yield the needed energy for heat and work? This raises the question, What other effects does spirit of wine produce on the body which may limit or impair its use as a food? In the following paragraphs an answer to this very wide question will be attempted, in the light of the most recent researches on the subject.

The Effects of Alcohol on the Body.—In general alcohol produces two kinds of effects, apparently very different from one another, dependent upon the quantity taken. In small doses it is a general stimulant, in large doses it is a narcotic poison. Here, at once, we are face to face with the broad fact that if alcohol is entitled to be classed as an energy-yielding food, its usefulness as such is strictly limited. Abundant illustration might be given of these two kinds of action. To an old person with enfeebled digestion a small quantity of brandy and water or whisky and water, given with food, enables the meal to be digested more easily. This is probably because the *slight* irritant effect upon the stomach, akin to the glow experienced in the mouth with the contact of the spirit and water, brings a larger supply of blood to the lining membrane and an increased flow of gastric juice from the stomach glands for digestive purposes. But if the dose is excessive, the irritation becomes so great that stimulation passes into paralysis, the quantity of digestive fluid becomes diminished, thick, and inactive, and perhaps is arrested, and patches of congestion appear on the stomach wall. These effects Dr. Beaumont saw with his eyes produced in the stomach of St. Martin (p. 601), after excess. The result was arrested digestion, wholly or partially. When these effects are marked, instead of the keener relish for food and increased appetite following the use of the small quantity, there are the loathing for food or simply the loss of appetite, the uneasy sensations about the stomach, the parched mouth, sickness, vomiting, and so on, so well known to too many. But the noticeable feature is that Dr. Beaumont observed the paralysing effect upon the stomach before St. Martin had any sensations, intimating to him any interference with digestion.

The stimulating effect of small doses and the depressing and paralysing effect of large doses of alcohol are also produced on the heart and circulation. With small doses the heart beats more quickly and strongly, and the flow of blood is thereby quickened through the body, to the brain, the muscles, and the skin. Moreover, the blood-vessels dilate, and the blood flows more readily through them. Thus the face flushes, the arteries of the temple throb, the skin, pinched and wrinkled and blue with cold, becomes softer, fuller, and ruddier, and a feeling of glowing warmth takes the place of the miserable shrivelled feeling the cold had induced. This is the stimulating action on the heart and circulation. But a large dose produces enfeebled and irregular action of the heart, and it has been shown that both in animals and man a large dose of alcohol may kill immediately by sudden stoppage of the heart's action. This, however, is due to the shock produced by the entrance of the large quantity into the stomach, by reflex action (p. 86), that is to say on the heart, and not by the spirit acting on the heart through the blood, though after the lapse of a little time a large dose would produce a like effect, acting through the blood.

In the same way a stimulating or a paralysing action is produced on the brain and nervous system in general, according to the quantity of spirit consumed. The lively imagination, the rapid flow of ideas, the sharpened wit, the freer discourse, the more generous enthusiasm, or it may be the more combative and argumentative spirit, are some of the stimulating effects of alcohol upon the nervous system, partly due to the increased supply of blood, owing to the quickened circulation, but also due to the direct action of the alcohol, circulating in the blood, on the nerve-centres. But the more markedly this stimulating effect is produced, the more near is one to the commencing of the paralytic action, when the loss of self-restraint indicates that the higher centres are beginning to succumb. The unsteady gait or speech proclaims the loss of the power properly to co-ordinate muscular movements for definite purposes, and rambling remarks, confused and stupid appearance, tell that the higher faculties of the brain are under the paralysing influence of the alcohol. It is the higher nerve-centres, those of the brain, that first experience the narcotic effect; the nerve-centres of the spinal cord are all affected later. Thus a man who cannot keep his feet may yet keep his saddle, if he is accustomed to ride, because it is the lesser brain or cerebellum (p. 93) that regulates the combined muscular movements necessary for walking, and that function is largely in abeyance, while he keeps the saddle owing to a reflex action (p. 86), the

stimulus derived from the thighs in contact with the horse acting on the nerve-centres of the spinal cord, which the alcohol has not yet overpowered. Even when the narcotic action on the nervous system is so pronounced that the man lies "dead drunk," insensible to kicks or blows, every muscle relaxed and powerless, one part of the nervous system may yet remain less powerfully affected, the medulla oblongata (p. 93), in which are the nerve-centres maintaining the action of the heart and the movements of breathing. It is not unless the dose has been sufficient to abolish their action also that death results, and it is usually the cessation of breathing that determines death, the heart continuing to beat a brief time longer.

Well then, it may be said, alcohol is safe so long as one does not exceed the quantity that simply stimulates. This might be admitted if it were possible to mark the point where stimulation ceased and narcotic action began. It is not easy to determine such a point, because one follows so hard on the track of the other. The depressing action, indeed, is the direct consequence of a certain degree of stimulation; it is exhaustion produced by the alcohol having goaded the organ, the nerve-centres, let us say, into expending more energy than it could speedily replace. In different individuals, too, the proportion between the two effects is very variable. In one individual the stimulating effect is hardly noticeable, it is so short-lived, and only the depression is prominent, even a small dose producing bad effects, while another seems to be unaffected except by large quantities. Indeed it is a question whether the stimulating effect is not in some senses actually already a paralysing one. The increased flow of blood to the stomach may be because the contact of the spirit with the stomach wall has partly paralysed the finer blood-vessels, has diminished, that is to say, the tone of their walls, so that they become more flaccid and more readily yield to the pressure of blood within them. The apparent stimulus to the heart may be because already a slight paralysing action is being exerted upon the restraining nerve of the heart (the pneumogastric, p. 96) and the exciting nerve of the heart (the sympathetic, p. 225) is not being properly and healthily restrained. It is certainly the view that the flushing of the face and the manifest more ready flow of blood to the skin are due to a certain degree of paralysis of the nerves (the vasomotor nerves, p. 233), which control the size of the blood-vessels, and so the pressure of blood easily dilates the vessels. Undoubtedly this is the explanation of the persistent redness of the face, nose, &c., of those who habitually indulge; the blood-vessels have lost their tone by the continued action of the spirit. If, again, the alcohol seems to stimulate the nervous system, one must not overlook the fact that, though ideas and speech become more rapid, control of them is less effective, and the healthy restraining influence of the higher nerve-centres is lessened. There is undoubtedly good reason for believing that the apparent stimulating action may be only a slight paralysing action in disguise, and, if so, it cannot be useful for a man *in health*, however useful it may frequently be in cases of disease. It has further to be noted that well-marked remote effects follow the habitual use of alcohol, not only in large doses but also in small, and apparently, harmless doses if frequently repeated. A man may take, for example, a nip of whisky or brandy without any apparent or actual effect, but if he is regularly in the habit, in connection with business transactions, for example, to have sundry and frequent nips a-day, though not one seems to have any effect upon him, yet in time slow changes are set up in various bodily organs, which become evident, it may be, only after years of continuance of the practice. These slow changes are of the nature of a degeneration, fatty or fibrous. The true structure of the organ or organs affected undergoes fatty degeneration, such as the muscular fibre of the heart, or becomes transformed into a fibrous character, such as is exceedingly common in the liver, giving rise to what is called "gin-drinkers'" liver, and also in the kidneys. The brain and nervous system may also be similarly affected. Now a man may become thus affected as a consequence of frequently-repeated small doses of spirits, who has never been known to be intoxicated, and whose friends are prepared to certify as a "strictly temperate man."

It will be well at this stage to note particularly what is the general tenor of the conclusions we have reached. They are these:—

1. *Alcohol is to some extent used up in the body, and may, therefore, liberate energy for heat or work, so that in a limited sense it may be classed as an energy-yielding food.*
2. *If alcohol is employed beyond certain small doses, it has injurious effects of a paralytic kind upon various organs of the body.*

Thus the first conclusion is qualified in a very important way by the second, for a food-stuff

which, if used, except in small quantity, will have an injurious effect, is scarcely to be considered of value as a food-stuff at all, it is little more than a drug.

Supposing the remarks that have been made as to the difficulty of marking a line between one kind of effect of alcohol and another, the evidently poisonous effect—supposing these remarks to be accepted as indicating the impossibility of saying to anyone, "You may take a certain quantity of alcohol without fear of harm," the question may yet be asked is it not possible to lay down a limit beyond which injury is almost certain to arise? If one cannot say, "You are perfectly safe within a certain limit," it will be at least of some use if one can say, "You are certainly in danger beyond another limit." This both Dr. Anstie and Dr. Parkes and others have attempted to do. It has been said that alcohol appears in the urine, breath, and sweat, some time after a quantity has been consumed. An endeavour was made to find what quantity, if any, could be given to a healthy man in twenty-four hours, *without any appearing in the urine.* As soon as any began to appear in the urine, that was accepted as an indication that more had been introduced into the body than could be disposed of, and that the introduction of more could almost certainly be productive of no useful effect. Dr. Anstie found that when a quantity exceeding one ounce and a half of pure alcohol (absolute alcohol) was introduced, *not at one time, but in 24 hours,* the limit was passed. Dr. Parkes and Count Wollowicz corroborated this in a very remarkable way by finding that in strong healthy men, accustomed to alcohol in moderation, they observed the beginning of injurious effects when a quantity of spirit was introduced in 24 hours, which contained between one and one and a half ounces of absolute alcohol. "Assuming the correctness of these experimental data," says Parkes, "which, though not extensive, are yet apparently exact, it is evident that moderation must be *something below* the quantities mentioned; and, considering the dangers of taking excess of alcohol, it seems wisest to assume 1 to 1½ fluid ounces of absolute alcohol in twenty-four hours as the maximum amount which a healthy man should take." The meaning of absolute alcohol is explained on p. 666. It, of course, is not used at all as a drink, and one could consume varying quantities of the different alcoholic drinks, without exceeding the 1 ounce of absolute alcohol, according to the percentage of alcohol they contain. The quantities can be calculated from the table on p. 667, where the varying percentage is stated. If whisky contains, in round numbers, only 50 per cent absolute alcohol, obviously 2 ounces of whisky will yield 1 ounce of absolute alcohol. An ordinary wine-glass contains generally about 2½ ounces of whisky, that is half a gill, and that quantity is beyond the limit of safety. The following table shows the relative quantities of the different drinks:—

1 oz. absolute alcohol is contained in				2 ounces whisky;		
1 ,,	,,	,,	,,	5	,,	wines like sherry and port;
1 ,,	,,	,,	,,	10	,,	,, claret and hock;
1 ,,	,,	,,	,,	20	,,	(1 pint) beer.

If a healthy man, then, take in 24 hours more than ⅘ths of a glass of whisky or brandy, 2 glasses port or sherry, 4 glasses (a half-pint) claret, or hock, or champagne, or a pint of beer, he takes a quantity which will produce effects on the bodily organs likely to be injurious, whether such effects are perceptible or not. For women the quantity is smaller, and any quantity to children in health is injurious.

The value of Alcohol to the Body.—Judged by the facts that have been briefly passed in review alcohol has no value for the *healthy* human body, *under ordinary circumstances. The taking of stimulants is, therefore, a question of individual taste and pleasure,* just as is the use of condiments, and as soon as the quantity taken for pleasure exceeds a certain small amount the region of possible danger is entered. Within the limit named, each person must be allowed to act according to his own judgment and inclination. There are, however, circumstances in which alcohol has, or is generally supposed to have, directly beneficial effects, circumstances which may be said to be more or less beyond the ordinary. What are these circumstances, and how far is the general idea concerning them correct is our next question?

It is a common idea that alcohol in some form is exceedingly useful when the body is subject to the pressure of great exertion. On this point there is now, fortunately, a great body of evidence, drawn chiefly from the experience of troops on the march and engaged in fighting. Dr. Parkes thus summarizes the results of his observations during the Ashanti campaign (1874). "The first effect of alcohol,

when given in a moderate dose (for example, what is equal to one fluid ounce of absolute alcohol), is reviving, but this effect is transient. The reviving effect goes off after at the utmost two and a half miles of additional march, and sometimes much before this; then the previous languor and sense of exhaustion not only return, but are sometimes more intense, and if alcohol is again resorted to, its effects are now less satisfactory. Its reviving power is usually not so marked; and its peculiar anaesthetic and narcotizing influence can usually be distinctly traced. The men feel heavy, dull, disinclined to march, and are less willing and cheerful." In the Red River expedition, led by Sir Garnet Wolseley, spirit rations were not issued. "The men were allowed a large daily ration of tea, 1 oz. per man—practically as much as they could drink; and, as I am now on this subject of bohea *versus* grog, I may as well state that the experiment was most successful. The men of no previous expedition have ever been called upon to perform harder or more continuous labour for over four months. . . . This expedition would have been a bright era in our military annals had it no other result than that of proving the fallacy hitherto believed in of the necessity of providing our men when in the field with intoxicating liquors." Sir Garnet Wolseley recommends substituting tea for rum, which results in increasing the efficiency and health of the men. There is abundant and remarkable evidence to the same effect. It appears, then, that alcohol by its stimulating effect may enable one to put forth a great effort for a very brief period. But it supplies no energy for overcoming the difficulty; it compels an increased expenditure of energy without supplying the material from which the energy is to be obtained. As a result in a brief period its effect is over, leaving greater exhaustion than before. It lessens the power of sustained work. Its action in this way may be compared to putting the "blower" on a low fire, which occasions a more rapid entrance of air and a temporary quickening of the dying flame. It is like the prick of the spur in the side of the tired horse, "eliciting force without supplying it." If alcohol is useful in fatigue, it is not when the work is being done, but *after it is over*, if restorative food can also be had. Then it may be like the "blower" over a low fire, *which has received a new supply of coal.* It stimulates the exhausted body to appropriate the benefits of the food, though even under these circumstances its use is inadvisable if food and rest are sufficient for the purpose.

Alcohol has been supposed to be useful during prolonged exposure to cold. The error here is easily pointed out. By its stimulating effect upon the heart, and the dilatation of the smaller blood-vessels it produces, it causes a freer supply of blood to the skin, and a consequent glowing sensation of warmth. This, however, is delusive. The spirit supplies no added heat worth noting, and the greater quantity of blood flowing in the skin exposes the body to a much increased loss of heat. We have seen (p. 309) that the heat of the body is maintained in a cold external atmosphere by contraction of the vessels of the skin, and a lessened supply of blood to the surface. Alcohol produces the opposite effect, and thus the body parts with its heat at a greatly increased rate. Its use under these circumstances is dangerous. But when the exposure to cold is over, and the person is amid comfortable surroundings, then, if necessary, alcohol may be used, and quickly arouses a feeling of warmth by permitting the blood to flow to the skin.

The opposite condition to cold, great heat is, it appears, also less easily borne with the use of alcohol, which, according to Parkes, predisposes to sunstroke.

The value of alcohol when food is persistently deficient has been already alluded to. In ordinary circumstances one would say the food ought to be as readily procurable as the alcohol, and at a much cheaper rate. In cases of disease, however, when the difficulty of taking food cannot be overcome, alcohol does often become an agent of great value. But if the use of alcohol were restricted to disease, few would be found to object. This circumstance connected with alcohol has, however, a bearing which may be indicated in closing these considerations.

Hitherto the author has not sought to express any opinion as to the value of alcohol. His desire has been simply to marshal the chief facts which scientific investigation has revealed, whatever these facts might be. The only opinion he ventures to offer, he indicates now, and because of its bearing upon the use of alcohol under circumstances of deficient food. It appears to him that the ignorance of a very large proportion of women of the working-classes, in particular, regarding the proper quality of food needful to sustain the body, their inability to prepare plain nourishing food in appetizing forms, their tendency to provide whatever gives least trouble, such as the almost

invariable tea bread and butter and bacon, which appeases the hunger without yielding sufficient for the repair of tissue and the liberation of energy for work, these form one of the main causes of the large amount of intemperance among the working-classes of the population. The men are not stimulated by their food, they are continually below par as regards energy for work, they know little of the buoyant elastic mood to which work is a delight, and consciously or unconsciously they feel a craving for something to stir them. So they take the spirits to raise the steam, and a vicious habit is speedily developed. "In many places," says Liebig, "destitution and misery have been ascribed to the increasing use of spirits. This is an error. The use of spirits is not the cause, but an effect of poverty. It is an exception from the rule when a well-fed man becomes a spirit-drinker. On the other hand, when the labourer earns by his work less than is required to provide the amount of food which is indispensable in order to restore fully his working power, an unyielding inexorable law of necessity compels him to have recourse to spirits. He must work, but in consequence of insufficient food, a certain portion of his working power is daily wanting. Spirits, by their action on the nerves, enable him to make up the deficient power at the expense of his body, to consume to-day that quantity which ought naturally to have been employed a day later. He draws, so to speak, a bill on his health, which must be always renewed, because, for want of means, he cannot take it up; he consumes his capital instead of his interest; and the result is the inevitable bankruptcy of his body."

One remedy for such a state of things is, not temperance or teetotal lectures, however valuable these may be, but disseminating broadcast among the people a knowledge of the uses and properties of foods, and their economic value, and teaching their daughters how to cook palatable and pleasant meals from plain and cheap materials, and how to serve them with decency if not with grace.

The value of alcohol in disease is undoubted. It would, however, serve no good purpose to consider it in this place. Its use has been now and again indicated in discussing special diseases in the first part of this work.

Wines from the Grape.

The Preparation of Wine.—Wine is the fermented juice of the grape. The fermentation takes place spontaneously and naturally speedily after the grapes have been crushed. The ferment is the same as has been noticed in speaking of the manufacture of alcohol, namely yeast, but it is not added as in producing alcohol or beer. It is already present on the exterior of the grape, and as soon as, by crushing, the juice and ferment meet one another, the process begins. The action is the same as that already described. The yeast acts upon the sugar, contained in the juice to the extent of 13 per cent, as shown in the table on p. 574, and converts it into alcohol and carbonic acid gas. Upon the extent to which the fermentation proceeds will sugar be left in more or less diminished quantity when it is completed. If very little sugar remains the result is a **dry wine**; but if a large quantity of sugar has been present in the grape juice, it will produce a larger proportion of alcohol. As soon, however, as a quantity of alcohol in a liquid has been produced above 16 per cent by volume, fermentation ceases, no further transformation of sugar will be produced, and the result will be a **sweet wine.** Now the more ripe the grape is the more rich is its juice in sugar. This ripening is produced by the influence of the sun's rays; and, therefore, it is in warm countries, such as Spain and Portugal, where the sweet strong wines, port and sherry, are prepared; and it is in more northerly regions, where the grapes can hardly be so fully matured, that the lighter and dry wines are produced—claret, hock, &c. Therefore, also, not only the climate influences the kind of wine which a particular district produces, but the quality of the wine produced in the same district, will vary with the season. Wine manufactured from grapes which have not arrived at the highest stage of maturity will be, on the same account, more acid than that prepared from fully ripe grapes. Some of the richest and most fruity wines, such as Tokay, are produced from grapes allowed to remain long on the vines, so that they develop a large amount of sugar and attain some degree of concentration of juice by the evaporation of water. In the Sauterne and other districts some of the richest wines are obtained by selecting the grapes, picking them from the bunches as they reach perfection.

In the process of manufacture the grapes are first crushed, formerly by being trodden by the feet, but now usually by mechanical means. When this has been done the juice, now termed **must**, may be drawn off and allowed

to ferment separately, or the whole mass is allowed to undergo fermentation together, the quality of the product varying with the process adopted. The fermentation sets in rapidly, and is completed in two or three days, or after a much longer time, according to the warmth of the place. During fermentation a froth collects on the surface owing to the rise of carbonic acid gas in bubbles. This is skimmed off several times. As the violence of the process diminishes the liquid begins to become clear by the settling of a sediment or "lees." This consists of exhausted ferment, precipitated organic matter and tartrate of potash, which the now alcoholic fluid cannot keep in solution to any great extent. The clear wine is now racked off and run into casks, where it slowly undergoes a further fermentation, and another quantity of sediment is thrown down. With the slow production of more alcohol, more tartrate of potash is precipitated in a crystalline form, called **argol**. In the course of this further fermentation, the wine is several times racked off and transferred to other casks. The material left in the fermenting vat, called **murc or mark**, is pressed, and the best of the liquid obtained may be placed in the casks, the muddier portion being used for inferior wine.

Now it is plain that during the process that has been indicated there is a multitude of circumstances, which will influence the character of the wine produced. If, after the grapes are crushed, the juice is expressed and fermented alone, a very different wine will be produced from that yielded by the fermentation of the juice with the skins, seeds, stalks, &c. When the juice alone undergoes fermentation a **white wine** is yielded, no matter though purple grapes have been used, for their juice is devoid of colour like the white ones. If, however, the skins are not removed, as soon as alcohol is produced it attacks the colouring matter in the skin, dissolves it out, and a **red wine** is the result. From the skins also, and seeds and stalks as well, an astringent material is derived and, thus, wine obtained from fermenting the juice along with skins, seeds, and stalks is more astringent. Again the quality varies with the rapidity of fermentation; for the slower this process, the more extensively do other changes occur besides the formation of alcohol and carbonic acid gas; these changes are the development of ethers, essential oils, &c., which give aroma and fulness to the flavour. On the other hand, if the process has been too rapid, time has not been given for these substances to form, produced as they are by slow oxidation changes, and the wine is thin and characterless. Sometimes alcohol is added to check the fermentation earlier than usual. Such wines, owing to the sugar not being nearly exhausted by the ferment, subsequently undergo slow changes which increase the bouquet and flavour of the wine, so that it matures with age. Wines which have had spirit added for such a purpose, or because they contained so small a percentage of alcohol as to be devoid of good keeping properties, are called **fortified wines**, while those which contain simply the alcohol due to fermentation are called **natural wines**. The wines of Portugal, Spain, Madeira, and the Cape are commonly fortified, those of France, Germany, and Hungary are more commonly natural wines.

Natural wines should not contain more than 7 to 13 per cent by volume of alcohol, while fortified wines contain 14 to 18.

The final process of wine manufacture is "fining." This is effected by the addition of isinglass or white of egg which carries down organic impurities and leaves the wine clear. It is allowed to remain at rest for several weeks after the addition of this agent, then it is racked off into another cask and is ready for bottling.

The Composition of Wine.—The composition of the grape has been shown on p. 574, and that of the juice before fermentation is, of course, similar. It contains water, sugar, albuminoid (nitrogenous) material, non-nitrogenous substances, other than sugar, such as gum, pectin, fat, &c., tartaric acid combined with potash, as tartrate of potash, fibre, and mineral matters, such as potash, soda, lime, magnesia, &c., in combination with sulphuric and phosphoric acid, and in the skins and stalks there are tannin and colouring matters. Now by fermentation the sugar becomes changed into alcohol and carbonic acid gas; the fermentation produces, besides, glycerin and succinic acid. Further, by the action of oxygen upon the alcohol produced, acetic acid is formed, and a substance called aldehyde which confers a peculiar smell and flavour. While, therefore, the acid of grape juice is mainly tartaric acid, the acids of wine are tartaric, acetic, succinic, carbonic, and formic, the last four resulting from the fermentation. There are also small quantities of fatty acids, and tannic acid when the skins and stalks have fermented with the juice, as in the case of red wines. Further, in the process of maturation of wine, ethers are formed by the action of

acids on the alcohol. They are formed slowly and in small quantity, being present, therefore, to greatest extent in old wines, and it is owing to their presence that old wines have the fruity aroma which makes them prized. An ether, produced by the action of a fatty acid on the alcohol, is œnanthic ether to which, though it is said to be present to the extent of only one part in 40,000, the characteristic smell of wine is mainly due. It is its presence in the spirit of wine—brandy—that gives to it its peculiar flavour and odour. By the action of the various acids upon the alcohol in new wine numerous ethers are produced, which process diminishes the alcoholic strength of the wine but develops its aroma. As already said it is only in old wines that these changes have occurred to any great extent. Much of the albuminous material of the juice of the grape disappears in the fermentation process, some remains and in time is precipitated by tannin, forming part of the crust of wine. Wine also contains less mineral materials than grape juice, because much of that material cannot be kept in solution when the liquid becomes alcoholic. It is in part precipitated as the fermentation goes on, and subsequently much mineral material is deposited in the crust, such as the bitartrate of potash (cream of tartar) and phosphate and tartrate of lime.

The changes which take place in wine, then, with age, are diminution or disappearance of sugar that may have escaped fermentation, diminution of alcohol and of acidity by the production of ethers and consequent improvement in aroma and flavour, and diminution of tannin albuminous and mineral matter by precipitation as crust; colouring matter is also deposited, so that the colour is also less dark.

There is a process, known as "plastering," employed during the production of wine which alters the quantity and kind of mineral substances present. It consists in dusting over the grape juice, before fermentation, sulphate of lime—plaster of Paris or burned gypsum. The object of this is to remove some of the acid flavour. Sherry and port are almost regularly subjected to such treatment, as well as certain wines of France and Greece. Tartrate of potash is removed by this means, tartrate of lime being formed and precipitated; but sulphate of potash is also formed; it is a bitter salt and remains in solution. The tartrate of potash thus removed from the wine is one of its most valuable salts. The process, according to Hassall, "deprives the wine, in fact, of a very valuable salt, substituting another salt of an injurious character." Wines are also frequently coloured artificially by the addition of burned sugar or vegetable colouring matters, and are also artificially flavoured by the use of elder flowers and other substances.

The following table from Church shows the constituents of the chief wines in ordinary use. The percentages of alcohol present in different varieties of wine is shown on p. 667.

Constituents of One Imperial Pint of Various Wines.

	Port.		Madeira.		Sherry.		Carlowitz.		Burgundy.		Champagne.		Claret.		Hock.	
	oz.	grs.	oz.	grs.	oz.	grs.	oz.	grs.	oz.	grs.	oz.	grs.	oz.	grs.	oz.	grs.
Absolute Alcohol,	3	218	3	218	3	147	2	35	2	18	1	343	1	306	1	219
Sugar,	0	359	0	175	0	236	none			10	1	120	0	9	none	
Tartaric Acid,		23		26		24		36		24		20		31		39
Acetic Acid,		12		18		12		19		17		10		18		18
Ethers,		6		5		4		5		6		5		6		4
Mineral Matters,		20		33		38		16		18		20		18		16

Besides the variation in the quantity of alcohol, one notes in this table the greater proportion of sugar in port, Madeira, sherry, and Champagne, and its absence in Carlowitz, Burgundy, claret, and hock, while the acidity of the latter is greater.

It does not fall within the purpose of this work to describe the various detailed differences between the various wines, sherry, port, Champagne, their special mode of production and so on.

The Use of Wines.—The action of wine on the body is determined to some extent by the quantity of alcohol contained in it. But it is said that the presence of ethers, mineral materials, &c., considerably alters the nature of its action, so that it does not so readily tend to produce injurious changes on the body as whisky or brandy or other strongly-alcoholic liquors. It is to be noted, however, that the strong wines, such as port, are usually taken undiluted, while whisky is usually drunk largely diluted; and thus those who take the fortified wines take alcohol in a more concentrated form than if they took whisky and water. Apart from the alcohol, the presence of sugar in some wines gives them a value as food-stuffs, and the mineral matters also occasionally are useful

to the body. It must not be forgotten that wines, almost without exception, interfere with digestion, if consumed to any extent (see p. 604), and interfere to a greater extent than the same quantity of alcohol, taken as whisky and water, would. This action is most marked in the case of the rich sweet wines, and least in hock and kindred wines. If wines are to be used at all, in health, preference should be given to the lighter French, German, and Hungarian wines, the clarets, hocks, and such a wine as Carlowitz, while sherry, port, Marsala, Madeira, and such wines should be in general avoided, and most particularly by dyspeptics, gouty and bilious subjects. These richer wines are often exceedingly valuable in enfeebled conditions, but are not advisable for ordinary employment. The Australian wines now freely employed afford an excellent supply of light wine for those who insist upon some such beverage daily. They are natural wines, of soft and delicate flavour, and with an aroma of their own. Anyone who believes he needs some stimulant to his appetite cannot do better than use such a light one, particularly in face of the difficulty of obtaining a good claret. If one really needs and derives benefit from such a stimulant with food, let him try a glass of good claret or similar wine, made up to a tumblerful with boiling water, and sipped throughout the meal. Sparkling wines, and particularly of a dry kind, and specially a dry Champagne, are often exceedingly useful in disease, when the stomach rejects food and other kinds of stimulant. The sparkle, due to the escaping carbonic acid gas, is grateful and often soothing to the stomach, and the restorative action of such wines is more rapid than that of still wines or ordinary spirits.

The Adulteration of Wines.—It is useless to speak of the value of wines without noting the enormous difficulties in the way of obtaining what is genuine. It does appear that actually good wine is almost beyond the reach of any but those who are able to pay a good price. The fact that wine is valuable under certain circumstances is, therefore, qualified by the fact that it is only procurable by the few. This will be sufficiently shown by the following extracts from Dr. Hassall's book on *Food and its Adulterations*. "Scarcely a natural sherry is to be met with in this country. The very finest and purest sherries imported . . . are fortified with grape spirit only, or with grape spirit, grape sugar, and grape colouring; . . . but the great bulk, we fear, of the sherries consumed in Great Britain, contain foreign spirit, foreign sugar, and foreign colouring, and are, in fact, mixed and adulterated." "A kind of sherry is manufactured in this country, the basis of which is pale malt and sugar-candy, a small quantity of French brandy and inferior wine being added to flavour the mixture." "Port wine is subject to a large amount of adulteration before it reaches this country; after its arrival here it is frequently subjected to further sophistication. Sometimes it is diluted, brandied, and then coloured by the mixture termed Jerupiga, or by means of logwood. The brilliancy of the colour is sometimes increased by means of alum, and, if turbid, it is cleared by gypsum, while increased astringency is imparted by means of oak-sawdust. Not infrequently peculiar flavours or bouquets are artificially communicated to port wine; the principal substances used for this purpose are extract of sweetbriar, orris-root, and cherry-laurel water."

Wines from Fruit other than the Grape.

Wine might be produced from any kind of fruit containing grape-sugar. The fruit is crushed like the grape, and the juice allowed spontaneously to ferment.

Cider is wine produced from crushed apples. After the fruit has been crushed, the juice is expressed, and then allowed to ferment, no yeast being added. The character of the liquor produced depends upon the kind of apple, whether it has been kept till fully mature, whether the juice has been expressed immediately after crushing, upon the length of time fermentation has been allowed to go on, &c. It contains usually from 5·21 to 9·87 per cent of alcohol by volume. If allowed to ferment too long, acid is readily produced, resulting in a sour thin liquid. In Normandy many varieties of apple are grown for the manufacture of cider.

Perry is prepared by a process similar to cider from pears. It contains usually about 7·26 per cent of alcohol.

Gooseberry Wine, Mulberry Wine, &c. may be prepared in similar ways from their respective fruits.

Beer and other Malt Liquors.

Preparation and Composition of Beer.—Malt liquors are prepared from malted grain, usually barley, prepared by the method already described at the beginning of the paragraphs on alcohol. The malt is mashed as explained in

these paragraphs, and the process carried on in a similar way to that for the production of alcohol, till the wort has been produced. The wort is then boiled, and here the first difference arises, consisting in the addition to the wort of hops. These are the female flowers of a plant belonging to the natural order *Urticaceæ*, the *Humulus lupulus*. They are grown to greatest perfection in Kent and Sussex. They contain an oil, the oil of hops, a bitter principle called lupulin, which are the two chief ingredients from the brewer's point of view, a resin, tannin, and mineral matters, &c. It is for the flavour and bitter, as well as for their preservative qualities, that hops are employed; and they impart an aromatic and tonic character to the infusion. The hops are added to the wort in the copper, in quantity dependent upon the liquor to be produced, for ale about 8 pounds of hops being added to one quarter of malt and 180 gallons of water, this quantity yielding 108 gallons of ale, water being lost in the course of the various processes. After being boiled the liquor is drawn off, strained, cooled to a proper fermenting temperature, and the yeast added. In three or four days the process is completed. The fermentation is not carried so far as in the production of alcohol, since in the manufacture of beer it is desired to leave some sugar unconverted. After fermentation the liquor is allowed to clarify, "finings" of isinglass being sometimes added to facilitate that process. The beer is then racked off into casks for use.

The kind of malt liquor produced depends upon the kind and quantity of malt used, the quantity of hops added, the extent to which fermentation is carried, and on various other circumstances. The greater the quantity of malt used, the higher is likely to be the alcoholic strength of the beer. Pale malt is used as a basis of all malt liquors, dark malts being employed in addition to give the colour to stout, porter, &c. Ale is manufactured from the pale variety only.

Malt liquors contain water, alcohol, and sugar, dependent upon the extent of the process of fermentation, albuminous substances of the malt extract, carbonic, acetic, lactic and succinic acids produced by the fermentation, bitter and colouring matters, and saline substances. The kind of water with which beer is brewed is understood to affect its quality. Thus the special character of Burton-on-Trent brew is believed to be due to some extent to the water, which is rich in mineral constituents.

The following is an analysis of a stout:—

Alcohol (by weight), ...	... 5·51	per cent.
Soluble Albuminoids,	... ·69	,,
Sugar, Dextrin, &c., ...	... 6·74	,,
Acetic Acid, ...	... ·05	,,
Lactic Acid, ...	... ·18	,,
Mineral Matters, ...	... ·37	,,

The following table from Church indicates the constituents of stout and ale:—

Constituents of One Imperial Pint of Ales and Stout.

	London Stout.		London Porter.		Pale Ale.		Strong Ale.	
	oz.	grs.	oz.	grs.	oz.	grs.	oz.	grs.
Water, ...	18	343	18	412	18	409	17	399
Alcohol, ...	1	74	1	10	1	12	2	18
Acetic Acid, ...		22		16		17		21
Extractives,[1]	1	25	1	3	0	372	2	42
Mineral Matter, .		22		18		10		30

Twenty ounces of beer (one pint) yield about one ounce of absolute alcohol.

Lager Bier (Munich) contains 5·1 per cent of alcohol, and 5 per cent of malt extract.

White Beer (Weiss Bier) contains 1·9 per cent of alcohol, and 5·7 of malt extract.

The Value of Malt Liquors.—Besides the alcohol, whose effects have been already discussed, malt liquors, as shown by the tables, contain undoubtedly nutritive materials in the shape of albuminoids, sugar, &c., derived from the malt extract. These materials are contained in largest amount in stout porter and strong ale. Such liquors thus possess stimulating, nutritive, and tonic properties, the latter being most marked in the pale ales. When taken in any quantity they tend to interfere with the due combustion of fats, and probably also carbo-hydrates in the body. In consequence a fat and bloated appearance is apt to be induced, more particularly as the liquor contains considerable quantities of fattening material in the shape of sugar. Moreover, the same interference with the natural action of the bodily organs leads to an accumulation within the system of imperfectly oxidized substances, resulting in impaired digestion, interference with the functions of the liver, gouty and bilious affections, nervous irritability and the like. According to the calculation already made (p. 672) the use of beer should be restricted to one pint per day. Stout and porter are frequently found valuable in the treatment of diseases of mal-nutrition, and they are in frequent use by nursing mothers. It would be well, however, if the employment of such agents in general weakness or disease were regulated by medical advice.

[1] This includes albuminoids, sugar, dextrin, &c., derived from the malt and hop extract.

SECTION III.—AIR, VENTILATION, AND WARMING.

Air.

The Necessity for Air.

The Atmosphere:

Physical Properties of Air—Effects of Temperature and Pressure—
Effects on the Body of Increased and Diminished Pressure—Mountain Sickness—Cupping Glasses.

The Composition of the Air—
Oxygen and Nitrogen—Difference in Quantity of Oxygen in a given Volume of Air according to Pressure and Temperature—Ozone.

Carbonic Acid of the Air;

Impurities in the Atmosphere—Dust in the Air—Germs in the Air—Observations with the Aeroscope;

Purification of the Air.

Ventilation.

Air of Confined Spaces:

Air Vitiated by Breathing—Smell as a Test of Impurity;

Quantity of Fresh Air required per head per hour.

Effects on Air of Burning of Candles, Gas, Fire, &c.;

Moisture in the Air.

Methods of Ventilation:

Ventilation by Diffusion of Air through Walls—Permeability of Walls—Construction of House Walls, Foundations, &c., in view of this;

Position of Openings for Ventilation;

Inlet Ventilators—Window Ventilation—Sheringham's Ventilator—Tobin's Tubes;

Outlet Ventilators—Ventilators in Chimney—Shaft Ventilators, Boyle's, Watson's, M'Kinnell's;

The Galton Grate;

German Stoves and Gas Stoves.

AIR.

The Necessity for Air.—In the first part of this work, in Section IX. A, the process of respiration has been considered, and the means by which air from the external atmosphere is taken into the lungs have been explained in detail. The reason for the introduction of air has also been briefly set forth, namely that oxygen is necessary for the life of the tissues, and that the blood flowing in the fine blood-vessels of the lungs obtains oxygen from the air introduced, and carries it to the tissues (see pp. 249, 257, and 261). Moreover, the purpose served by the oxygen derived from the air is sufficiently indicated in the early portions of Section I. of Part II., where the energy of the body is shown to be derived from food-stuffs by a process of combustion, or oxidation, or union with oxygen (see pp. 527 and 531). The food-stuffs themselves contain oxygen as part of their chemical constitution, some to a great extent, like starch and sugar, others to a less extent, like fat; and thus they may undergo partial oxidation without any added quantity of oxygen being supplied. But none of them contains sufficient oxygen for complete combustion either outside or inside the body.

Thus sugar	contains	51	parts	of oxygen	in every	100
starch	,,	49	,,	,,	,,	100
fat	,,	10	,,	,,	,,	100

But these are totally insufficient quantities of oxygen to effect complete combustion of the food-stuffs, &c.

For 100 parts of	sugar	require	103	of oxygen for complete combustion.	
,, ,,	starch	,,	120	,,	,,
,, ,,	fat	,,	293	,,	,,

There exists, therefore, the necessity of introducing into the body a very large quantity of oxygen wherewith the food-stuffs may combine to yield energy for work and heat; and this large quantity is introduced from the atmosphere by the process of breathing. We have already commented (p. 619) on the fact that different climates require different foods, not only because more heat is necessary to maintain

the bodily temperature in one—a cold climate, and less in another—a hot climate, but also because sufficient oxygen cannot readily be introduced in the hot climate, where the atmosphere is rarefied, to oxidize such foods as fat; while it is easily introduced in the cold climate, where the atmosphere is condensed.

It is important then to consider the nature of the atmosphere, under varying circumstances, since it plays so important a part in the processes of life.

The Atmosphere is the gaseous envelope which surrounds the earth. At a distance from the earth, not positively determined, it ceases; the distance being usually set down at from 40 to 45 miles on an average. Now air has weight, though that is not immediately apparent. If a flask, in the condition in which it is usually called empty, but when it is really filled with air, be balanced on a scale-pan, and then by means of an air-pump if the air be withdrawn, and the flask be then replaced on the pan, it will be found lighter, the loss being the weight of air removed. It has been found that 100 cubic inches of air weigh 31 grains at a temperature of 32° Fahr. and when the barometer registers a pressure of 30 inches of mercury. At this same temperature and pressure a cubic foot of dry air weighs 566⅘ grains. Air can be compressed; its particles which tend to expand, to repel one another, can be pressed more closely together, in which case the bulk of air can be diminished. At the surface of the earth, then, at the level of the sea, the atmosphere exerts a certain pressure, the pressure or weight of the 45-mile layer of air between the limit of the atmosphere and the given place. The layer of air nearest the earth is bearing the weight of all the layers of air above it; and since air is compressible, the layer next the earth will be more compressed, will be more dense, that is to say, than any other layer higher in the atmosphere. So that as one ascends in the atmosphere the pressure and density will diminish. The **pressure of the atmosphere** at the sea-level is, as a mean, equal to the pressure of a column of mercury 29·92 English inches high. So that in a tube from which air has been withdrawn mercury will rise to that height by the atmospheric pressure. This is the height of the barometric column. The pressure of this column of mercury is equal to that of a column of water 32 feet high, water being about fourteen times lighter than mercury. This pressure is in round numbers equal to 15 pounds to the square inch. On everything at the earth's surface this pressure is exerted, on every part of our bodies also, on the outer portion of the body, and by the windpipe and bronchial tube on the inner surface of the lungs, &c. We feel no weight because the pressure is everywhere uniformly distributed. If one descends a mine the atmospheric pressure increases; as one ascends a mountain the pressure diminishes. If a very high ascent is made, whether by climbing a high mountain or ascending by a balloon, various effects are produced on the body, which taken together form what is called **mal des montagnes, or mountain sickness.** Among these symptoms are loss of appetite, thirst, sickness, vomiting sometimes of both bile and blood, frequent and difficult breathing, quickened irregular weak pulse, great muscular fatigue, headache, depression, and dimness of vision, congestion of the blood-vessels of the skin, and bleeding from the nose, eyes, ears, bowels, &c. These effects are partly experienced at a height of 10,000 feet, and almost certainly at an elevation of 17,000 feet, though they appear more quickly in some persons than in others. The causes of these symptoms are partly mechanical and partly chemical. The diminution of pressure outside the body, that within the blood-vessels and cavities of the body remaining the same, is sufficient to account for the rupture of blood-vessels; while the rarefied condition of the atmosphere, resulting inevitably in deficient oxygen being obtained, accounts for most of the others. Similar effects have been produced by submitting persons, in cylinders constructed for the purpose, to more or less rarefied atmospheres. On the other hand, when the body is submitted to an atmosphere whose pressure is greatly above the normal, as in a diving-bell, other effects are produced, diminution of rapidity of pulse and of breathing, increased appetite, &c., and ill effects follow a very high pressure. Whenever anyone has been subject to a very high pressure, as by working in a diving-bell or in caissons in deep water, return to the normal pressure should be effected gradually, not suddenly.

The effects of pressure on the body are illustrated by the action of cupping-glasses. These are small bell-jars, and they are applied in the following way. A penholder or similar piece of wood has a small piece of lint or cotton, &c., wrapped round one end, which is then dipped in spirit of wine, to make a small torch. The cupping-glass is placed upon the skin and raised on one side to permit of the penholder being passed inside the cup. The spirit is then lighted,

and the flame introduced for an instant into the cup and immediately withdrawn, when the cup is instantly pressed upon the skin all round. Vapour from the flame drives the air from the cup, and after the torch is withdrawn this vapour condenses. Air not being able to enter, a partial vacuum is created. Thus the pressure on the skin covered by the mouth of the cup is much less than that beyond it. In consequence the skin and flesh beneath it rise up into the cup, and the blood-vessels of the skin become congested with blood. The effect of this is to draw the blood from deep parts, and thus cupping-glasses used to be employed to withdraw blood from the seat of deep inflammation.

The **density of the air** varies also with the temperature. A high temperature causes the air to expand, and therefore to become lighter—that is, of two equal volumes of air at different temperatures that of the high temperature will weigh less than that of the low temperature. It is changes in the temperature due to local causes that occasion winds, the currents produced being the means for re-establishing equilibrium.

It is a remarkable circumstance that air has little power of absorbing heat, while it readily transmits it. Thus the heat-rays from the sun pass through the air without heating it to any great extent. When these rays fall upon the earth, it absorbs them and the earth's surface becomes warm. The layer of air in contact with the earth is then heated, because of its contact with the earth, and rises, cold air flowing in to replace it, to be warmed and in turn to rise, and thus a movement of air is created. The result of this is evident. If the air absorbed the heat-rays of the sun to any extent it would become unbearably warm and too rare for breathing purposes; while by the earth becoming warm and gradually giving out its heat, sudden changes are modified, and a degree of warmth kept up after sunset, coolness gradually, not suddenly, setting in.

The Composition of the Air.—The atmosphere consists chiefly of two gases, oxygen and nitrogen, not in a state of chemical union, but simply in a condition of mechanical mixture. It is somewhat singular that, in spite of varying conditions of place, climate, &c., the proportion of these two gases remains practically uniform, namely:—

20·9 per cent of oxygen, and } by volume.
79·1 ,, ,, nitrogen,

If the estimation is made according to weight, then 100 parts of air contain

23 parts of oxygen, and
77 ,, nitrogen.

Now it has been said that, at a temperature of 32° Fahr. and a pressure of 30 inches of mercury, a cubic foot of dry air weighs 566¾ grains. Taking the proportion of oxygen and nitrogen by weight as 23 and 77, then of this 566¾ grains, in round numbers,

436½ grains are nitrogen, and
130¼ ,, oxygen.

Total, 566¾

But it has been said that air expands with heating. A cubic foot of air at 32° Fahr. will be more than a cubic foot at 80° Fahr.; in other words, a cubic foot of air at 80° Fahr. will weigh less than a cubic foot at 32°. It weighs, indeed, only 516¼ grains, containing fully

397½ grains nitrogen.
118¾ ,, oxygen.

Then as to pressure, the cubic foot of air at a pressure of 30 inches contained

130¼ grains of oxygen;

but at a pressure of 25 inches of mercury, equal to an ascent in the air of about 5000 feet, the cubic foot of air is lighter and contains only

108·6 grains of oxygen.

Thus suppose a man breathing fifteen times a minute in a cold atmosphere, and obtaining thereby a certain quantity of oxygen. In a warm atmosphere, if he is to obtain the same quantity of oxygen, he must breathe faster. Similarly, if he breathes at a certain rate at the sea-level, and thereafter ascends a high mountain, his breathing must be quickened if he is to introduce the same quantity of oxygen into his blood.

Why does a man in good health usually feel buoyant, active, and able to do a considerable amount of hard work in cold weather? while in hot weather the same man feels dull, less disposed to activity, and certainly indisposed to hard work. The facts that have been stated supply part, at least, of the explanation. Hard work means increased liberation of energy in the body, increased oxidation changes, implying increased supplies of oxygen, obtained with comparative ease in the cold weather, when with every cubic foot of air breathed he introduces 130¼ grains of oxygen, but obtained with greater difficulty in hot weather, when he can introduce less and less oxygen with every cubic foot of air breathed, as the temperature rises, and thus cannot liberate energy in his body with the same rapidity.

In addition to oxygen and nitrogen air contains 4 parts of carbonic acid gas in 10,000, the quantity increasing slightly up to an elevation of 11,000 feet above the sea-level and then decreasing.

Watery vapour is also constantly present, varying in amount with the temperature of the locality, the higher the temperature the greater being the quantity of watery vapour which the air will hold. Thus at a temperature of 100° Fahr. each cubic foot of air will hold nearly 20 grains of water, while at freezing temperature each cubic foot will hold only 2 grains. As the air cools down from 100° Fahr. to freezing-point the watery vapour will, in consequence, separate out from it and be deposited. This is the explanation of the formation of dew. When the sun has set, the heated air rising from the earth deposits moisture as soon as it comes into contact with colder strata. When air at a certain temperature contains as much watery vapour as it can hold, it is said to be saturated for that temperature. If the temperature rise it can take up more vapour, and has got some drying power it had not at the lower temperature.

Besides the gases named and watery vapour there are present in air other substances, some of them gaseous and others solid; but these are rather to be considered impurities, and will be spoken of under that heading. It will be of much interest to note the value of these different constituents of the air.

Oxygen is a gas, colourless, and without taste or smell. It is the most abundant of all the elements in nature, and unites readily with almost every substance. When a substance unites with oxygen it is said to become **oxidized** and the process is called **oxidation**. This process may occur slowly or rapidly. When it occurs rapidly, the heat produced by the action is very apparent and the substance may burst into flame, and thus heat and light are produced. Thus when a fire burns, as already explained (p. 527), the carbon of the coal unites with the oxygen of the air. When a candle burns the substance of the candle unites with the oxygen of the air, the carbon of the substance uniting to form carbonic acid gas (CO_2, p. 651) with the oxygen, and the hydrogen of the substance uniting with oxygen to form water (H_2O, p. 636). When we burn coal-gas to give us light, the same thing happens. A very simple but very instructive experiment may easily be performed. Let a little wire stand be made so that two pieces of candle can be fixed upon it, one low down, the other near the top. Let this be set upon a large dinner-plate, let us say. Then let a bell-jar be taken, or such a glass shade as is used to cover a large pot of ferns or such like plants, of a size that the plate can hold. Light the pieces of candle, cover with the bell-jar, and pour a little water on the plate, to make a layer sufficient to cover the lip of the jar all round, so that no fresh air can enter. At first both pieces of candle will burn quite brightly. Soon drops of moisture will form on the inner surface of the glass jar, the moisture formed by the union of the hydrogen of the candle oil with the oxygen of the inclosed air. After some time the light will be perceptibly feebler, and the flames will become smaller, the lower one more slowly than the upper. By and by the upper flame will die out, the lower still burning feebly. If the bell-jar be lifted when the lower one is about to die out, it will immediately start again burning with vigour. The meaning of all this is that the oxygen of the inclosed air has gradually been consumed, and as the jar contained increasingly less and less the flames became feebler, because oxidation was less rapid. As the burning went on, not only watery vapour but carbonic acid gas was produced, which will not support combustion but will extinguish it. This gas, though heavier than air, rises to the upper part of the jar, because heated gas ascends and pollutes the atmosphere where the higher flame is burning, and as soon as sufficient has been produced it drowns it out, while the lower piece of candle still finds oxygen in the lower and colder part of the jar. When this lower piece is also about to go out from want of oxygen and from presence of carbonic acid gas, the raising of the jar supplies fresh air and it begins to burn again vigorously. As already explained this process of oxidation goes on in the living body, alike of animals and men, as part of the absolutely necessary processes of life. With a diminished supply of oxygen only feeble life could be maintained, just as only a feeble flame could burn. So that if a man or an animal were placed in a confined space, into which no fresh air could enter, his life would gradually become extinguished like the candle flame. The atmosphere, then, is the common source from which are drawn supplies of oxygen to maintain combustion for yielding heat and light, &c., and for the maintenance of life.

Furthermore the oxygen of the air is one of the most active of purifying agents. All organic matters exposed to the air undergo an oxidiz-

ing process, by which they are reduced to simple substances. Putrefaction and decay are processes of this kind carried on by the agency of minute living organisms. Thus all dead animal or vegetable matter undergoes oxidation and is reduced from useless and perhaps hurtful forms to valuable and harmless substances. So that the atmospheric oxygen is one of nature's great purifying agents.

One can obtain pure oxygen from substances which contain it in large quantity. Thus chlorate of potash, which is a chemical compound of chlorine oxygen and potassium, contains it in abundance. If chlorate of potash be heated in a flask oxygen is given off and can be led by a tube and collected in a jar over water. If a piece of wood with a bright glowing end be thurst into a jar of oxygen, it will immediately burst into flame and burn with great rapidity and brilliance. Such rapidity of combustion is not desired, neither is it possible for living beings to breathe anything like pure oxygen for any time with safety. While, therefore, it is the oxygen that is the valuable constituent of the atmosphere, it is necessary to be present in a diluted state.

The **nitrogen** of the atmosphere is a gas which performs the needful duty of diluting the oxygen. It also is a colourless gas without taste or smell. It does not burn and will not support combustion. A lighted candle thrust into a jar of nitrogen will immediately go out, not because the nitrogen extinguishes it, but because of the absence of oxygen to enable it to burn. It is an indifferent gas, with no active properties. In the atmosphere it acts, therefore, simply as a diluting agent for the oxygen. Its value, however, when in chemical combination, specially in the formation of organic substances like albumin (p. 536) has already been insisted on.

Ozone is a form in which oxygen exists, in which it has a peculiar smell and a very high degree of chemical activity. It is readily produced in air by passing electric sparks through it, and it is naturally produced in the atmosphere by the discharge of lightning. The activity of ozone in the work of oxidation and in the destruction of organic substances is much greater than that of simple oxygen, and an atmosphere rich in ozone is certain to be one of great purity. Perhaps this accounts for its absence from the air of towns, and its presence in the fresh air of the country.

Carbonic Acid Gas of the Air.—If, then, some one may say, with every act of combustion oxygen is consumed, and if life implies the removal of oxygen from the atmosphere, the quantity of oxygen daily removed from the atmosphere must be enormous. Moreover all this means not only the consumption of oxygen but also the production of carbonic acid gas, and this gas (which has been considered on p. 651) is inimical to life. In two ways the atmosphere is daily being vitiated to an enormous extent. This is all quite true. Thus De Chaumont makes the following calculation: "At the lowest estimate there cannot be less than 300,000,000,000 cubic feet of carbonic acid gas generated in London in a year from combustion and respiration, or a mean of 822,000,000 per day, or 34,250,000 per hour, or more than 9500 cubic feet per second. Now this is sufficient to double the normal amount of carbonic acid in 23,750,000 cubic feet of air per second, or in about 14 cubic miles every twenty-four hours, or more than 5000 cubic miles per annum. This represents a mass of air of the area of the metropolis, but extending upwards to ten times the height of the Himalayan Mountains." It has been estimated that in Paris one hundred millions of cubic feet of carbonic acid gas are daily produced, one-tenth by the respiration of animals and human beings, and the remainder by processes of ordinary combustion. How is it that under such circumstances all life does not speedily cease from the surface of the globe? The marvellous economy of nature is not unequal to the gigantic task of disposing of the enormous mass of carbonic acid daily produced upon the earth's surface. In the open air the carbonic acid gas is allowed to accumulate nowhere. By diffusion (see p. 258) the carbonic acid produced rapidly mixes with the atmosphere, while variations in temperature producing currents of air and so forth make the mixture still more rapid and thorough. Finally, while men and animals are constantly removing oxygen from the atmosphere and then returning it, combined with carbon, as carbonic acid gas, plants are as persistently reversing the process, *under the influence of sunlight* (see p. 258), removing the carbonic acid gas from the atmosphere, appropriating the carbon, to build it up into their structure, and returning the oxygen to the air. So that the purification of the atmosphere by vegetable life can always keep pace with its defilement by animal life, wherever the laws of nature are allowed their undisputed sway. As a consequence the remarkable fact has been shown that everywhere, *in the open air*, the proportion of carbonic acid

gas is pretty nearly the same, as the following list shows:—

Over the open sea the proportion is			·032	per cent.
At Portsmouth	,,	,,	·032	,,
,, Manchester	,,	,,	·037	,,
,, Aldershot	,,	,,	·040	,,

,, Top of Mont Blanc	,,	,,	·061	,,
,, Chamounix	,,	,,	·063	,,

Impurities in the Atmosphere.—Besides oxygen, nitrogen, carbonic acid gas, and watery vapour, there are many other substances found in the atmosphere, some gaseous and some solid, dependent upon locality, upon the nature of the earth's surface, upon the proximity to towns, manufactories, &c., upon animal and vegetable exhalations, and so on. The gaseous impurities are specially the product of manufactories, chemical works, &c., and are such as sulphurous and sulphuric acid, hydrochloric acid, ammonia, nitric acid. The two first of these result in quantity from the burning of coal, because of the sulphur it contains, and from the burning of gas made from common coal. The late Dr. William Wallace, city analyst for Glasgow, expressed the opinion that a million tons of sulphur contained in coal, are burned in Great Britain annually, producing fully three million tons of oil of vitriol. There is also a large quantity of vitiating gases passed into the atmosphere from manure and refuse heaps, from decaying organic matter, animal and vegetable, from sewage and so on. Salt is found present in air, derived from the ocean, even at considerable distances from the coast.

The nature and extent of the solid foreign impurities are more easily estimated. The fact that the atmosphere everywhere contains myriads of particles is matter of common observation. When a beam of sunshine passes into a darkened room through a chink in the shutter, the pathway of the beam is marked out by a white track through the darkness, a pathway formed of multitudes of dancing particles. But for the presence of these minute foreign substances, the pathway of the beam would be invisible. They catch the light and reflect it, and thus reveal the course of the light (see p. 388). If a lighted spirit-lamp be held under the beam, the white beam will at once appear as if cleft in twain by a dark gulf, as if it had been cut in two. The hot flame has destroyed the dancing particles immediately above it, and the light is passing across a space from which the particles have been removed, so that its pathway is no longer visible. Beyond the hot flame the track is white as before. This shows that the majority of these particles are organic in their nature since they will undergo combustion with such effects. How by various observers and by varied experiments it was finally established that the air-ocean which surrounds our earth was nearly everywhere teeming with life, like the liquid ocean of the sea, though of microscopic size, has been already detailed on p. 385 and subsequent pages. One of the most complete investigations into the character of atmospheric particles was conducted, less than fifty years ago, by a German, Ehrenberg, who investigated the exact nature of the elements of common dust found in houses, libraries, museums, towers, the Bernese Oberland, the High Alps, Lebanon, and the Himalayas. Later Dr. Douglas Cunningham, of the Indian army, made a most elaborate report to the Indian government on the foreign materials present in air, and numerous observers, German, French, and English, more particularly Dr. M. P. Miquel, of the observatory of Montsouris in the southern portion of Paris, have made careful and detailed observation on the particles present in atmospheric air at varying seasons and under a variety of circumstances.

The results of all these observations go to show the continual presence of particles, derived from the mineral, vegetable, and animal kingdoms, in the atmosphere. The wind carries into the atmosphere, even to great heights, sand, dried particles of mud, particles of coal, iron, &c., varying with the geology of the country and with the nature of the manufactures carried on in it. Dust raised by wind-storms may be carried over great distances. In Berlin atmospheric particles have been found, which had been carried from the deserts of Africa. The enormous numbers of these dust particles, invisible to the unaided eye, which may be present it is almost impossible to conceive. John Aitken, F.R.S.E., using a method of counting them, devised by himself, estimated that

In fair weather each cubic inch of external air contained	2,119,000
In rainy ,, ,, ,, ,, ,,	521,000
While in a room ,, ,, of air contained	30,318,000
And ,, ,, ,, ,, from near the ceiling contained	88,346,000

"It does seem strange," says Mr. Aitken, "that there may be as many dust particles in 1 cubic inch of the air of a room at night when the gas is burning as there are inhabitants in Great Britain, and that in 3 cubic inches of the gases from a bunsen flame there are as many particles as there are inhabitants in the world."

An apparatus employed for collecting particles present in the atmosphere is called the **aeroscope**, of which one form is shown in Fig. 268. The centre piece contains a disc perforated by holes round the side, and having in the middle a microscopic slide, fixed by clips. In front of this is fitted a funnel-shaped piece, the inner end of which comes to a fine point, and opens just in front of the centre of the glass slide. Behind is fitted a tail-piece which keeps the funnel always opposite the direction from which the wind is blowing. The aeroscope is fitted to the top of a post, fixed in the ground, so that it may revolve with the wind. A drop of glycerine is placed on the centre of the slide. The air blowing into the funnel is directed by the fine point on to the drop of glycerine, which thus catches many of its contained particles. The air then escapes through the holes in the disc. Dr. Cunningham used such an arrangement, and exposed different slides to the wind for a varying time, twenty-four hours or more, and then examined the slides with the aid of a microscope. Fig. 269 exhibits the contents of a part of one of his slides. By such means the air has been shown to contain, besides the mineral substances, mentioned above, grains of starch, the pollen grains of various plants, spores of cryptogamic plants, hairs of nettles and other plants, fragments of woody fibre, cotton, fragments of vegetable tissue, minute insects, diatoms, scales of insects, hairs of rabbits and bats, plumes of feathers, minute animals of the worm class, and so on. In towns fragments of shoe leather, particles of horse-dung, fibres from clothing, &c., have easily been recognized, picked up by the wind from the streets. All kinds of germs, which have been described in detail on p. 387 have also been found.

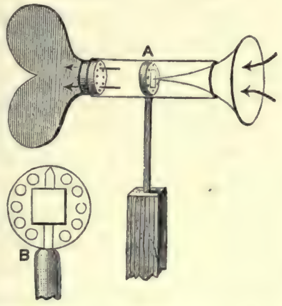

Fig. 268.—Aeroscope of Dr. Cunningham.

The use of the ordinary aeroscope, figured in Fig. 268, does not permit the number of atmospheric particles present in a given quantity of air to be counted. This more recent and more elaborate methods permit being done. Miquel in particular, has devised most ingenious methods of doing this, with the object of discovering how atmospheric germs were affected in number by rain, temperature, &c.

He found that the number was much diminished after rain. He also showed that if the air were not too dry, the number increased as the temperature of the air rose, but if the heat of the atmosphere passed a certain point, the number rapidly fell. After prolonged drought, moreover, the number diminished, moisture as well as heat being necessary for germ life. With the advent of cold weather, rapid diminution occurred. Thus from May to September the number of germs in the atmosphere about Montsouris Observatory was large, but with the advent of December the fall occurred and the number remained small till the advent of warmer weather in May. Montsouris is situated in the outskirts of Paris, so that the wind coming in one direction blows over the open country, while when it blows from another it passes

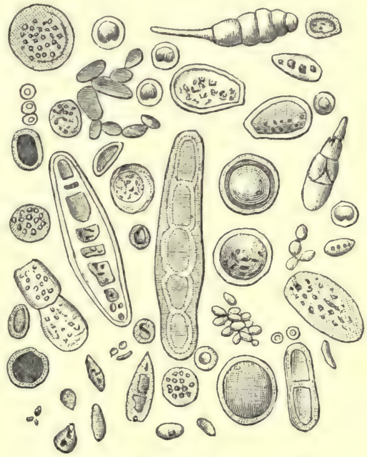

Fig. 269.—Atmospheric Organisms.

over the city. Miquel found that the wind which passed over Paris before reaching the observatory was always more laden with germs, picked up from the city, than that blowing direct from the country. He also always found the air more vitiated in the centre of the city than in his suburb. Moreover Miquel tried to find whether there was any discoverable relation between the amount of infectious disease in Paris and the number of germs in the atmos-

phere. He obtained the weekly returns of deaths from infectious disease in the city, and compared them with his tables of atmospheric life. At first he found no very striking similarity. But he bethought himself that it was unlikely that there would be any relation between infectious disease and the number of germs in the atmosphere about his observatory in the suburbs. So he transported his apparatus to a house in the centre of the town and proceeded to make observations. Then he obtained a very remarkable set of coincidences, for he found that whenever the weekly returns showed an increase in infectious disease his observations showed a rise in the number of air germs, and when the number of cases of disease fell, so also did the estimated number of organisms in the air. On several occasions the resemblances were very well marked, a great and rapid rise in the amount of infectious disease having an exact counterpart in a sudden great increase in the number of atmospheric organisms.

The Purification of Air of confined spaces is effected best by proper ventilation by methods already described. A large number of substances, solid, liquid, and gaseous, have also been used to effect the same purpose by chemical means. Thus dry charcoal, preferably animal charcoal, placed in saucers or other shallow vessels in the apartment, absorbs vapours and oxidizes animal emanations contained in them with great rapidity. It is said to be specially useful for air polluted with sewage gases. Solutions of Condy's red fluid, permanganate of potassium, are used in the same way. Carbolic acid in solution may also be used, placed in saucers, or sprinkled about the apartment. Chlorine gas destroys organic substances, and may be slowly disengaged in a room from chloride of lime moistened with water and placed in a shallow dish. If it be moistened with dilute sulphuric acid (oil of vitriol) the gas is disengaged rapidly. The fumes, however, are very irritating, and cannot be employed to any extent in an occupied room as the other substances can be. Iodine has also been used, being diffused through an apartment by allowing it to fall drop by drop on a hot plate and by other means. Sulphurous acid is employed for the same purpose by burning ordinary sulphur, but it also cannot be employed in an occupied room. Charcoal, Condy's fluid, and chlorine actually destroy by oxidation organic matters in contact with them, but the weak solutions of carbolic acid do not. The carbolic acid will arrest the growth of organisms, but preserves rather than destroys them. Some of these substances may be employed in the filter or troughs of inlet ventilators, and the ingoing air may thus be purified. The purification of rooms after infectious disease is described on p. 396.

VENTILATION.

Air of Confined Spaces.—Air, it has been already noted, undergoes constant defilement from the respiration of men and animals, from the burning of various substances, and by emanations from decaying animal and vegetable refuse. When natural laws are allowed full play, this vitiation is rapidly counterbalanced. The air rapidly mixes, animal and vegetable substances are speedily oxidized by the action of the oxygen of the air and by sunlight, and a normal standard of purity is easily and constantly maintained. If, however, the operation of natural laws is hindered or set aside, as by air being inclosed within confined spaces, so that free communication with the external atmosphere is prevented, then the impurity of the air is liable to become speedily marked. Wherever air is thus confined, and is at the same time liable to impurity by respiration, &c., it becomes necessary to provide special means of communication with the outside air, for the removal of the vitiated air and its replacement by a fresh supply. To such means the term ventilation is applied. To understand the full meaning of the word, it is necessary to have a correct appreciation of the nature and extent of the alterations thus produced on the air of inclosed spaces, and the effects of the alterations upon the healthy body.

Air Vitiated by Breathing.—Suppose a completely inclosed space inhabited by one or more persons, what changes does the air undergo? Oxygen is removed from it, carbonic acid gas is added to it, the amount of watery vapour is increased, and, besides, the air has added to it certain animal products, difficult to define, given out from the lungs and given off in the perspiration, &c., from the surface of the body. It is to these organic matters that the stuffy odour of an atmosphere is due, which has been rendered impure by the respiration of men or animals. The extent to which these various changes are injurious was shown long ago by an experiment performed by an Italian, Polli. He placed animals in inclosed spaces, containing the same quantity of air, but one of the spaces had an arrangement by which, by means of lime, the carbonic acid gas and moisture pro-

duced by the breathing of the animal were absorbed, another was provided with charcoal which absorbed and destroyed the organic exhalations, while a third had no arrangement for removing any impurity at all. Thus the air in the first space would be gradually deprived of its oxygen, and would have organic impurity added to it, the air in the second would have its oxygen diminished and its carbonic acid gas and watery vapour increased, but would have organic matter destroyed, while the air of the third would become impure by the abstraction of oxygen, and the addition of carbonic acid gas, watery vapour, and animal exhalations. The animal living in the last-named atmosphere died first, that living in the air from which carbonic acid gas was removed died next, and that in the atmosphere from which the organic matter was separated out by the charcoal lived longest. The organic products of respiration, &c., are then not only those which give the stuffy fœtid odour to ill-ventilated rooms, halls, &c., but also those which are most injurious to health. The unaided nose, therefore, is well fitted to warn of danger.

An atmosphere might contain abundance of oxygen, but if the carbonic acid gas were greatly in excess, it would still be an atmosphere fatal to life, for the excess of carbonic acid gas in the atmosphere would prevent the same gas produced in the body from being given off, indeed the gas would pass inwards to the blood from the external atmosphere. In such a case death would result from poisoning by carbonic acid gas, the symptoms being those of a narcotic poison, no struggling, no gasping for breath, but unconsciousness deepening into coma. On the other hand an atmosphere might be cleared of excess of carbonic acid gas without new supplies of oxygen being furnished to it. If deficiency of oxygen became very marked death would again result, but not from narcotic poisoning by carbonic acid gas, but from want of oxygen. It is in this circumstance that the hurried laboured breathing, and violent convulsive spasms of suffocation occur.

The facts then of special practical importance are that an atmosphere containing a proportion of carbonic acid gas produced by respiration, and charged, therefore, with organic impurity, will become inimical to life, even when it still contains a good proportion of oxygen. Thus the candle, which goes out in the bell-jar, is extinguished not for want of oxygen, for the atmosphere in which it goes out contains still from 15 to 18 per cent of oxygen, but because of the presence of the carbonic acid. If any arrangements existed for withdrawing this latter gas, the candle would continue to burn for a longer period.

The practical question comes to be what amount of impurity due to respiration may exist in the atmosphere of confined spaces without injurious effects on health, at what degree of impurity does an atmosphere become hurtful? As soon as that question has been answered, one proceeds to inquire by what methods one may prevent the air of inclosed spaces reaching this degree of impurity.

A considerable number of experiments have been made to determine the first question. Thus Dr. Angus Smith had a leaden chamber made, air-tight, in which he could sit for varying times, and from which samples of air could be drawn off for analysis. Professor de Chaumont found, as the results of experiments made by him, that the sense of smell gave pretty accurate indications as to the degree of purity of the atmosphere. These results are expressed in the following table:—

Ordinary atmospheric air contains ·04 per cent CO_2.

When the air contains *an added*	·0183	per cent	it gives no perceptible smell.
,, ,, ,,	·03894	,,	it smells rather close.
,, ,, ,,	·06322	,,	,, close.
,, ,, ,,	·08533	,,	,, extremely close.

If we add these quantities of carbonic acid gas produced by breathing to the quantity, ·04 per cent, already in the atmosphere, we find that when air contains ·06 per cent of CO_2 it is on the brink of becoming undesirable for breathing purposes; in round numbers when ·02 part CO_2 has been added to every 100 of the atmosphere by breathing, the limit has been reached for air that is to be considered pure. Now ·02 per cent is equal to ·2 per 1000 or 2 per 10,000. So if we express the above table in parts per 10,000, we shall have the following:—

Ordinary air contains 4 parts CO_2 in 10,000.

Air containing	6	,,	,,	does not perceptibly smell.
,, ,,	8	,,	,,	smells rather close.
,, ,,	$10\frac{1}{2}$	,,	,,	,, close.
,, ,,	$12\frac{1}{2}$	,,	,,	,, extremely close.

It must be remembered, however, that this only applies to air to which the added quantity of carbonic acid gas has been supplied by breathing. For the smell is not due to the carbonic acid gas; it is caused by the organic impurity also present in expired air. So that the quantity of organic impurity, which is detected by smell, is simply used as a rough index of the amount of CO_2 also present, both having been produced by the same process of respiration.

When the sensation of smell is taken as a gauge of the impurity, it must not be forgotten that one's sensation of smell is reliable for this purpose, only when one passes from fresh air into the confined space. Everyone is aware how very soon one gets accustomed to an atmosphere which seemed almost unbearable the moment one stepped into it. We often remain in a room or other confined space without being aware of the impurity which the atmosphere has attained. If we pass out from the room into the fresh air we are impressed with the pleasant freshness of the external air and involuntarily draw in deep drafts of it. If after a minute or two we pass back to the room, &c., which, in the meantime, we may suppose has been kept without any ventilation, we are at once conscious of the foulness of the air, we have been so long breathing without any consciousness of its impurity. Now it is not merely that we become accustomed to the atmosphere so far as our sensations are concerned, but the whole body adapts itself to the impure atmosphere. This has been easily proved in the case of the lower animals. Claude Bernard, the French physiologist, placed a sparrow in a bell-jar, which was inverted over mercury, so that no fresh air could enter. He found that it expired after three hours, before that time gradually becoming feebler and more languid till death occurred. If taken out at the end of the third hour it speedily recovered. But if an active sparrow were suddenly introduced, at the *end of the second hour*, into the jar, it died at once. That is to say the first sparrow could live a full hour longer in an atmosphere, to which it had become accustomed, and which was fatal to another sparrow suddenly introduced to it. The body can accommodate itself, if it has the opportunity, to a vitiated atmosphere to a certain extent; but this accommodation can be effected only by a depression of the bodily energies, by a lowering of the general vitality, which manifests itself in the languor, headache, listlessness, and lack of vigour so common to those who are accustomed to vitiated atmosphere for prolonged periods. A person of ordinary acuteness of smell may then judge accurately enough of the condition of the air of a confined space, provided he steps into it from fresh air, but the one who has been sitting in the vitiated atmosphere is least likely to be aware of its hurtful condition.

An atmosphere, then, to be considered of a healthy character, should not have more than ·2 part per 1000 of carbonic acid gas *produced by respiration*, or, as the phrase is, of respiratory impurity.

Quantity of fresh air required per head per hour.—Suppose one man to occupy a room 15 feet long, 10 feet broad, and 12 feet high. When empty this room would hold 1800 cubic feet of air. We shall suppose that with carpets, hangings, furniture and the man himself so much space was occupied that the quantity of air was only 1500 cubic feet. Suppose no air were to be able to enter or leave the room, we can easily calculate in what time the atmosphere would be polluted, by the breathing of the one man, to the limit we have named, 0·2 of a cubic foot of respiratory impurity to every 1000 cubic feet of air, that is 0·3 of a cubic foot to the 1500 cubic feet in the room. According to observations made by Pettenkofer, of Munich, an adult man produces in one hour 0·7 of a cubic foot of carbonic acid, when at rest; women produce less and children less also in proportion. Dr. Parkes and De Chaumont take 0·6 of a cubic foot as the fair average production by men, women, and children per head per hour. So that in half an hour, taking this average, the apartment named would contain 0·2 of respiratory impurity per 1000. At the end of an hour 0·6 of a cubic foot of respiratory impurity would be present in the 1500 cubic feet of air, that is 0·4 per 1000. It is clear that if this atmosphere is to be reduced to the limit of 0·2 per 1000, it would require to be diluted by an equal bulk of fresh air, it would require to be mixed with 1500 cubic feet of fresh air, and even then it would be on the verge of an improper degree of impurity.

To put it in another way, at the beginning of the hour the man enters the chamber containing 1500 cubic feet of fresh air, suppose that there is a current of fresh air passing through the room just sufficient to renew the whole air of the room once in the hour, that is to say, during the hour, 1500 cubic feet of air pass through the room. Then at the close of the hour the atmosphere will contain 0·2 of respiratory impurity per 1000. Suppose the man remains in

the room; he starts the second hour with 0·2 per 1000 of respiratory impurity already present, that is 0·3 of a cubic foot in his 1500 cubic feet of air; he produces during the hour 0·6 of a cubic foot of respiratory impurity, which, added to what was present at the beginning of the hour, makes 0·9 of a cubic foot of respiratory impurity. To reduce this 0·9 to 0·2 per 1000, 4500 cubic feet of air would be needed. But the apartment contains only 1500 cubic feet. So that if the atmosphere of the chamber is to be kept down to the proper limit, it will be necessary that during the second hour 3000 cubic feet of fresh air enter it. If a current of fresh air equal to this amount has passed through the room during the second hour, then at the end of it the respiratory impurity will be still at the limit of 0·2 per 1000. Suppose the man remains another hour, the conditions are the same as during the second, so that after the first hour he needs a supply of fresh air equal to 3000 cubic feet per hour. Whatever the size of the room one takes to begin with, it will be found on calculation, supposing the average production of carbonic acid gas to be 0·6 of a cubic foot per head per hour, and the respiratory impurity to be limited to 0·2 per 1000, that 3000 cubic feet of fresh air are required per head per hour. This calculation, it is to be observed, is made for persons at rest. De Chaumont says: "Of course in rooms occupied by persons in active work, more would be required, as from 50 to 100 per cent more impurity would be evolved; therefore, in ordinary workrooms, from 4000 to 5000 cubic feet per head per hour would be necessary, and in unhealthy trades 6000 to 7000. Some of my experiments were made in hospitals, occupied for the most part by ordinary cases, and I was thus enabled to compare the results with those in barracks occupied by healthy men. . . . It took nearly *one-third* more air to keep the atmosphere sweet in hospitals, so that we may safely lay it down that in ordinary cases no hospital ward ought to have less than 4000 cubic feet per head per hour, and that in cases . . . of epidemic disease the amount ought to be greatly increased; indeed practically the amount ought to be unlimited, so that many kinds of disease might be advantageously treated in the open air. This is proved by the great success of tent hospitals, both in time of war and in time of peace. In Germany this open-air plan has been practically tried to a great extent, and with very gratifying success."

De Chaumont gives a table, which I give here, to show the length of time it would take to bring the air in unventilated spaces of different sizes to the limit of purity (0·2 of a cubic foot of respiratory impurity per 1000 cubic feet of air):—

No. of Persons.	Size of Space in cubic feet.	Time taken to bring Air to Limit of Purity. hours.	minutes.	
One man	10,000	3	20	
,, ,,	5,000	1	40	
,, ,,	1,000		20	
,, ,,	600		12	
,, ,,	200		4	
,, ,,	50		1	
,, ,,	30			36 seconds.

The following table, showing the quantity of impurity per 1000 cubic feet of air produced by one man in inclosed spaces of different sizes, and the quantity of fresh air needed per hour to dilute the impurity to the standard limit, is derived from Parkes:—

Quantity of Air Space in cubic feet.	Quantity of CO_2, produced by Breathing, per 1000 cubic feet of Air per hour.	Amount of Fresh Air needed during the First Hour to dilute CO_2 to 0·2 per 1000.	Amount of Fresh Air needed to dilute CO_2 for every Hour after the first.
100	6·00	2900	3000
200	3·00	2800	3000
300	2·00	2700	3000
400	1·50	2600	3000
500	1·20	2500	3000
600	1·00	2400	3000
700	0·85	2300	3000
800	0·75	2200	3000
900	0·66	2100	3000
1000	0·60	2000	3000

Effects on air of the burning of candles, gas, &c.—The calculations that have been made have permitted no allowance for the burning of fires, candles, oil-lamps, or gas; and as these cannot burn without their due supply of oxygen, a considerable increase in the amount of fresh air will be necessary. Thus it has been calculated that one sperm or paraffin candle will produce in one hour half the quantity of carbonic acid gas produced by a man at the same time, so that two candles will necessitate an hourly supply equal to that for one man. A good oil-lamp produces rather more than ½ cubic foot of carbonic acid gas per hour—that is about the amount produced by one man, and a good gas-burner (which burns 3 cubic feet of gas per hour) will produce 6 cubic feet of carbonic acid gas per hour. Therefore one man and one good oil-lamp will together produce in one hour nearly 1·2 cubic feet of carbonic acid gas. To bring this down to the proper limit 6000 cubic feet of fresh air would be required per hour, no matter

what were the size of the space. Calculating on the same basis, one man and one gas-burner would produce 6·6 cubic feet of carbonic acid gas per hour, necessitating 33,000 cubic feet of fresh air per hour. This is an enormous quantity; and it must be remembered that the burning gas, while it yields much more carbonic acid gas than a man breathing, does not yield organic impurity, so that the necessity of diluting it to the same extent as respired air is not nearly so urgent. It has been thought that 1800 cubic feet of air per hour would be necessary for each cubic foot of gas burned. If 3 cubic feet per hour are burned, that implies 5400 cubic feet of fresh air for that purpose alone, which, added to the 3000 necessary for the man, amounts to 8400 cubic feet per hour for one man with one gas flame burning.

One pound of oil requires about the same amount of fresh air as 10 feet of gas. If the same amount of light is yielded by each, gas, oil-lamps, and candles render the air impure nearly to the same extent, so that there is not much to choose between them. As a matter of fact it appears that gas gives more illuminating power with a smaller consumption of atmospheric air than wax candles. But when lamps or candles are used, they are usually so placed as to throw the light in a particular direction, where the illumination is desired. The necessary illumination is obtained at a much less consumption of material, and the air suffers much less in consequence, not only because of a diminished production of carbonic acid gas but also because of a lessened amount of heat and moisture.

Another point, which requires consideration in the question of the quantity of fresh air to be supplied per hour, is the burning of fires. A fire in an ordinary fireplace, in a room 20 feet long by 20 broad by 12 high, is assumed to burn 8 lbs. of coal per hour. For proper combustion this coal requires 1280 cubic feet of air. It is to be noted, however, that the draught up the chimney created by the burning coal causes a current of air to the fire much greater than is necessary for the consumption of the coal. Probably twice the quantity of air, needed for combustion, is carried up the chimney; and 14,000 to 20,000 cubic feet of air is considered a moderate computation of the amount that will pass up the chimney of such a fire in one hour. In the burning fire, therefore, there is a powerful agent in the renewal of the air in an apartment.

Moisture of the Air.—Another factor enters into the calculation of the quantity of fresh air needed per hour in inclosed spaces, and that is the quantity of moisture the air contains. Watery vapour, it has been stated, is contained in fresh air in proportion to the warmth of the air. Air as it is breathed out from the body is saturated with watery vapour, and we know that if the air be breathed on a sheet of cold glass, the vapour will be deposited in the form of minute drops of water. Moreover watery vapour is constantly being given off from the body in the form of perspiration, usually invisible perspiration. The importance of this in regulating the temperature of the body has been referred to on p. 309. If the air surrounding a person be dry, that air can absorb moisture to a large extent, to a greater extent in proportion to the warmth of the air. If, on the other hand, the air is already saturated with moisture it cannot absorb more, evaporation cannot take place from the body, and the moisture will be readly deposited on the body itself. If the external atmosphere is cold this deposit of moisture will have the effect of rapidly cooling the body, because water is a better conductor of heat than air, and the thin film of water on the body will cause the body rapidly to part with its heat to the cold atmosphere, resulting in chilling. If the external atmosphere is warm and saturated with moisture, the body cannot part with its heat properly, and a feeling of oppressive sultriness and languor is produced. Now in a confined space, owing to the watery vapour given off from the lungs and from the skin, the air will by and by become saturated with watery vapour, and discomfort will be occasioned. This will happen sooner or later according to the size of the space. Therefore to prevent saturation occurring a fresh supply of air is needed. The burning of lights produces also watery vapour, and if any liquids be in the inclosed space, vapour will pass off from them, saturating the air more rapidly than if only the evaporation from the body of a person were occurring.

The degree of moisture in the atmosphere which is most comfortable to the body has been determined to be 75 per cent, complete saturation being assumed to be 100. The actual quantity of vapour in the atmosphere, sufficient to produce this degree of moisture will, of course, vary with the heat of the atmosphere. Thus at a temperature of 63° Fahr., 4·7 grains of water per cubic foot of air produce this degree, and at a temperature of 65° Fahr., 5 grains. That is to say the higher the temperature of the air the more moisture it can hold,

without exceeding the degree (75 per cent) most agreeable to health.

Now it has been calculated that an adult man will raise the degree of moisture in a space, containing 500 cubic feet of air at 60° Fahr., from 70 per cent to saturation in one hour, and with a space of 1000 cubic feet, occupied by one person, 3000 cubic feet of fresh air per hour would be necessary to maintain the degree of moisture at the proper level.

In short we have found that, if the air of an inclosed space is to be kept at a proper standard of purity, as regards the quantity of carbonic acid gas produced by respiration, 3000 *cubic feet of fresh air per hour, for every individual present, ought to be supplied, and that this same quantity of fresh air will keep the air of the apartment at a proper degree of moisture; and further we have found that, for every cubic foot of gas burned, an added* 1800 *cubic feet of air are necessary, while a fire needs a large additional quantity.*

The question, therefore, is now how can this large quantity of air be duly supplied without perceptible currents being produced, that is to say, without draughts?

For what does 3000 cubic feet of air per hour imply? It means that suppose a room affording only 500 cubic feet of air space, the whole air of the room must be renewed six times each hour, and if two persons occupy the room, the air requires renewal twelve times per hour. This could not be borne. If the room had 1000 cubic feet of air space, then the air needs renewal only three times per hour for one person, but six times for two. On the other hand a room having 3000 cubic feet of air space (and a room $15 \times 18 \times 13$ would have that, even allowing 500 cubic feet of space for furniture) would require renewal only once during the hour for one person, twice for two, thrice for three and so on. Renewal four times during the hour is the most that can be borne in a climate such as ours, where it is scarcely possible at any season to have the house freely open to the external air. It is, therefore, readily seen that the problem of ventilation is a very difficult one when one is dealing with small inclosed spaces, and also very intricate when one is dealing with halls, lecture-rooms, school class-rooms, &c. For in the small space the air must be renewed often, yet without draughts, and in the halls, &c., one expects large numbers of persons, and must again provide for frequent renewal of air. The problem, on the other hand, is simplified when one is dealing with, for example, a modern house, of large rooms with lofty ceilings, spacious hall, and so forth, in ordinary circumstances perhaps occupied by only six or eight persons at a time. But if on the occasion, let us say, of an evening party, the rooms are crowded with guests and many lights are burning, the difficulty of fresh air at once arises. It remains then to be seen how, in ordinary circumstances, these difficulties are met.

It is not, it must be observed, that a person living in a large space needs less fresh air than a person living in a small space, they both need the same, namely 3000 cubic feet per hour, but it is that this 3000 cubic feet of air can be so introduced and distributed in the large space that its entrance is not observed, while in the small space it is very difficult without elaborate arrangements to introduce the needful quantity without the establishment of unpleasant currents. High ceilings are, therefore, desirable, for it has been found that, if the height is less than 10 feet, currents of the circulating air are certain to be perceptible to a disagreeable extent. As regards floor space, it is desirable that the minimum should not fall below 50 to 60 square feet, per person, if possible not below 80 square feet. Taking 60 square feet and allowing the height of the room to be a minimum of 10 feet, that would allow 600 cubic feet of air space for each individual. This is the space allowed in barracks for each soldier, but 200 only is allowed in a cell of Chatham Convict Prison. If we take 600 as a standard, a room 10×12 and 10 feet high would contain 1200 cubic feet of air, and this should not contain more than two persons. One can, therefore, easily calculate the number of persons, inhabiting one room, that will be consistent with a fair standard of purity of air, by simply multiplying the length of the room by the breadth and the result by the height and dividing by 600. It will be noticed that to provide 3000 cubic feet of air per hour for one person in such a space, implies renewing the air of such a space five times per hour, implying careful arrangements for proper ventilation.

Methods of Ventilation.

Methods of ventilation are divided into natural and artificial. The artificial include those means adopted in large establishments, halls or churches, by which by means of some pumping or suction apparatus air is driven or drawn through the building. The natural methods are those which depend upon the ordinary

physical laws, which everywhere regulate the movements of air and wind. It is not the object of this work to consider the artificial methods, always requiring elaborate machinery, but to point out the principles that should guide the arrangements for securing natural ventilation, and the main simple contrivances employed for that purpose.

Ventilation through Walls.—A quite unsuspected means of natural ventilation has been pointed out by Pettenkofer of Munich, who showed and proved by an interesting experiment that air readily passed through the walls of a house, so that an exchange of air was effected between the atmosphere within and that without the house. This is effected by the physical process called diffusion of gases, already referred to on p. 258. Two gases will mix if placed in contact with one another, and they will also mix though divided from one another by a membranous partition, and they will mix with great facility through a partition of baked clay or other porous substance. It is in accordance with the same physical law that when there is the atmosphere of a confined space, the air of a room, separated by a wall—a porous partition—from the outside atmosphere, exchange and mixture should be effected through the wall. Such exchange will take place much more rapidly if the two atmospheres are at different temperatures, as they almost invariably are, the air of the room being warmer than that of the outside. Thus Pettenkofer found in the case of a room with brick walls, in which every crevice and crack had been carefully closed, and which contained about 2700 cubic feet of air, that the whole air of the room was completely renewed once in an hour by diffusion through the walls, when there existed a difference of temperature equal to 34·2° between the inside and outside air. When the difference of temperature fell to only 7° Fahr. the change of air fell to 780 cubic feet per hour, and with the same difference the change was increased to only 1060 cubic feet when a window 8 feet square was opened. This exchange through walls was illustrated by Pettenkofer in a very striking way by the blowing out of a candle through a 9-inch brick wall. If a brick be covered all over except at the two ends with a coating of wax, or other impervious material, and if then at each end there be fixed a small funnel, the junction of the two being also covered with wax, and if a lighted candle be placed near the opening of one funnel, and the person blow into the other funnel at the end of the brick, the candle flame will readily be made to flicker, and after a little with an effort may be blown out. By surrounding a piece of wall with an air-tight box and otherwise making an arrangement similar to that described with one brick, though on a large scale, the candle may still be blown out. It has been found by two German observers that with a difference of temperature of 4° Fahr. air passed, by this natural process of diffusion, through one square yard of wall, at different rates according to the nature of the material of which the wall was built, as the following table shows:—

1 Square Yard of Wall built of	Cubic Feet of Air per Hour passing.
Sandstone	4·7
Quarried limestone	6·5
Brick	7·9
Tufaceous limestone	10·1
Mud	15·4

It is clear then that the ventilation of a house will to a considerable extent be affected by the material of which it is built. A brick-and-mortar building is very pervious to air, so also is sandstone. Cement walls on the other hand are much less porous, and it is questionable whether they make a healthy house. If they are impervious to water from without, they are equally impervious to water from within. The watery vapour, given off by breathing which would be to some extent absorbed by the porous wall, is not absorbed by the impervious one, but the moisture deposits on the colder wall, collects and runs down and makes a very unpleasant house.

The permeability of the walls will also be affected by papering, painting, and varnishing. "Coating with water-glass," says Lang, "probably in time completely destroys the permeability of a wall, so also does oil-paint, while new, although the cracks which come in the course of time make a considerable difference. When I state that oil-paint is the principal agent in preventing the diffusion and passage through the walls of the watery vapours which originate in domestic processes and respiration, it will be necessary for the science of hygiene to decide whether water-glass and oil-paint will have to be condemned. Size-colours also lessen the permeability considerably, and in proportion to the strength of the size; that used by me was so feebly sized that it lost colour, and yet the amount of air passing through was lessened by one-half; the smallest loss of permeability occurred when lime-colours were used."

In the next place it is also plain that a house

with several free walls will be more easily ventilated in this way than one with less. A detached villa, for example, will permit of this diffusion taking place from all sides.

Then it will be noticed that this natural means of ventilation will come most prominently into force during the colder periods of the year, just at those periods when one seeks to close up, in a wholesale fashion, all ways for the entrance of cold air from the outside and to heat up the interior. The great difference thus produced between the temperatures within and without will develop the diffusion to its greatest amount. A remarkable case in a London house is related by Mr. W. N. Hartley of King's College, London, "which gives a distinct proof of the much greater passage of gas through the walls in winter than summer. A small room occasionally used was noticed sometimes to have an unbearably bad smell; this was never noticed in summer, nor in winter unless a fire was lighted in the room; the drainage was suspected and examined, but was found perfect, yet here was this extraordinarily foul air making its way into the room, whenever the interior was warm and the exterior was cold. The cause was a dust-bin built against one of the walls, and the filtration [diffusion] of the air through this and the house wall into the room."

This natural means of ventilation is in every way desirable, since it permits an exchange of air quite free from draught, and since the passage of the air through the wall robs it of solid impurities. At the same time if walls are porous to air they are also porous to water, and while it is desirable to build them of material that will not interfere with a valuable means of ventilation, it is also necessary so to build them as to afford adequate protection from the weather. Moreover walls permeated with moisture deny a passage to air. Again walls whose pores are occupied by air are bad conductors of heat, air being a very bad conductor, and thus such walls do not readily conduct the heat from the dwelling. On the other hand water is a good conductor of heat, and if the walls are saturated with water, they become good conductors and are very active in reducing the temperature of the house. It is for this reason that houses with damp walls give one so marked a sensation of chilliness. The porosity of walls is, therefore, largely retained and the disadvantages of their being penetrated with water largely reduced by thickness. In a wet climate a thick wall will prevent the access of damp and the loss of heat, and in hot climates it will hinder the heating up of the house by the rays of the sun, under both circumstances assisting in the maintenance of a mean temperature. Double walls would answer the purpose admirably, the two walls being separated by a space of 1½ to 3 inches, and bound together at proper intervals. The passage of damp would be prevented, the layer of air would be an admirable non-conductor, and exchanges between the outer and inner atmospheres would not be interfered with. For exactly similar reasons walls should be lathed before plastering, the plaster, being by the lathing separated from the wall, acts as an inner wall, an air-space existing between the two. Walls plastered without previously being lathed are usually damp.

Not only does exchange of air take place between the outside and inside of a building but it takes place also by the same natural processes between the various portions of a building. The atmosphere of a room is, therefore, affected not only by diffusion between it and the air outside through the walls but also by diffusion through its floor and ceiling between apartments above and below. We all know how an escape of gas in one room is detectable in a room above. This is of special importance in houses provided with cellars, which are so often allowed to lie in a state of dirt and disorder and with no proper means of ventilation. If the cellars are underground, as they so often are, this becomes a matter of very serious importance, demanding careful attention.

Further there is retained by the soil a large quantity of ordinary air and other gases, and the very reasons which should induce one not to interfere with the natural ventilation occurring between the free air of the outside and the air of inhabited houses, would cause one to take steps to prevent exchange of air between the atmosphere of a house and that of the soil on which it is built. This is specially the case, if the ground is a made-up one, which may contain all sorts of refuse, decaying animal and vegetable matter, and effluvia from drains, &c. Such exchange is prevented by the house being provided with a foundation of cement and by a layer of damp-proof material, in the wall above the level of the ground, which adjoins the wall. Slates of glazed earthenware, slates embedded in cement, in asphalt, &c., are used to provide such a "damp-proof course" as it is called, which with the layers of cement ensures both against the passage of soil-air into the house and the rising of damp.

Still further to prevent gases from the soil

entering the house, it is well to ventilate the space between the foundations and the basement floor by means of gratings let into the walls. The need of such precautions is abundantly shown by the fact stated by Pettenkofer, that persons were poisoned in a house by coal-gas, though no coal-gas was laid on to the house. The gas had escaped into the soil at a distance from the house, had travelled 20 feet under the street, and had thus gained access to the foundations and cellars of the house. A case occurred near London in 1874, where coal-gas gained entrance to houses by permeating the soil, the gas coming from a damaged main. It accumulated to such quantity that finally an explosion occurred which demolished one of the houses.

Openings for Ventilation.—We have thus considered the natural exchange that goes on between the warm air of a room and the colder air of the outside, and we have seen that it may be a valuable means of ventilation; what other means usually exist? It is very commonly the case that there is no special provision whatever for the letting in of fresh air, or the letting out of foul air, beyond what can be effected by the opening of a door or window. If a fire is burning it ensures the passing of a current of air through the room. The fresh air enters by every available crack and crevice or ill-fitting joint, under the door, through the key-hole, and by the sides of the window. A sufficiently plentiful supply may gain admission, but it is in an undesirable way, cold currents being produced, and it is in a way not under control. Moreover, with the entry of the air is the entrance of dust, and indeed the direction of the current along a wall, &c., is frequently shown by the dust-track. Now if a sufficiently large opening, communicating with the outside, be made to permit the free entrance of the necessary supply of air, all these irregular air currents will be abolished, and the flow along the open channel can be regulated at pleasure, while various filter arrangements can be employed against dust. Let anyone hold a candle flame opposite the keyhole of the door, in a room which has no special inlet for air, the deviation of the flame will show a strong current. Now let a window be raised slightly to permit free entrance of air, the behaviour of the candle-flame will show that the current through the keyhole has ceased. It is, therefore, desirable that special openings should be made, certainly for the inlet of fresh air, and also for the outlet of foul air, even though a fire acts admirably as an extractor of air.

What, then, are the general principles that should guide one as to the position, size, shape, &c., of these inlet and outlet openings?

The position of air openings is regulated by the fact that heated air rises. The foulest air in a room is nearest the roof, and this in spite of the fact that the foul air contains a considerable proportion of carbonic acid gas, which is a heavy gas, heavier than ordinary air. It is only its greater degree of warmth, as it is expired through the mouth, that causes the polluted air of respiration to ascend. If this foul air, after ascending towards the roof, became cooled, the carbonic acid would descend and would more readily have the opportunity of being breathed over again. The outlet for foul air should then be placed as near the roof as possible. If it were possible, so far as comfort is concerned, to admit the fresh air by an opening near the floor, it would be a natural arrangement. The cold air would enter below, the foul heated air would escape above. But this is not a suitable arrangement, as it would tend to cause chilling of the feet of the occupants of the room. For similar reasons it is undesirable that fresh air should enter at any level which would render it possible for it to strike against any part of the body of a person in the room, and, therefore, it is customary to arrange the inlet opening so that the fresh air enters above the level of persons standing in the room, and to direct it towards the roof, so that it spreads out and is diffused through the apartment.

Inlet Ventilators.—If the chimney is deemed a sufficient means of withdrawing the foul air, then only an inlet tube needs to be provided. It may be placed in the wall near to the ceiling, and it should be so arranged as to direct the current of entering air towards the roof, against which it strikes and is so broken up into a fine shower of fresh air, draughts being thus prevented.

Window Ventilation.—The simple contrivance of having holes cut in one of the topmost panes of a window, which may be opened or closed by a revolving glass disc, on the hit-and-miss principle, is good enough so far as the admission of air is concerned, but it admits direct currents and so occasions draughts. Of window-pane ventilators a better form is that with louvred panes, by means of which the air is directed upwards. Another simple contrivance is to have a slit made in the lower bar of the upper half of the window, running the whole length of the bar, so as to leave a space about a quarter of

an inch at the place where the upper bar of the lower sash and the lower bar of the upper sash meet. This permits of an entering current and directs it upwards. Another method is to fit a bar of wood, about three inches broad or thereby, to the bottom of the lower sash of the window, so that the lower sash is kept raised a couple of inches or so, and yet no air permitted to enter below. The effect of this is that the two sashes do not meet in the middle, as they do when the window is completely shut, and air is thus permitted to enter in an upward stream. If a room is fitted with double windows, ventilation is very easily carried out by keeping the lower sash of the outer window open a few inches, and the upper sash of the inner window down a few inches. The air entering at the bottom of the outer window passes up in the space between the two windows, and enters the room above. This arrangement has a double advantage. The single window is the cause of a great loss of heat to the room. Thus, suppose a room of ordinary size, containing 3000 cubic feet of air, and having two windows with a surface of glass equal to 30 feet. One square foot of glass, it is said, will cool 1·279 cubic feet of air as many degrees per minute as the internal air exceeds the external in temperature. If such a room is occupied by six persons, its air will require renewal four times per hour at least, and the total cooling effect of the glass will, in these circumstances, be such as to represent a constant lowering of temperature of the air in the room equal to 9·5°. Now if the windows be double much of this loss of heat will be prevented, the outer panes preventing the inner being constantly robbed of their heat by the cold external air. Moreover, the entering air, as it passes through the space between the two windows before gaining the room, will be somewhat warmed by contact with the inner panes, and thus the double benefit will be gained. It is always, however, preferable, except where double windows exist, to have a special inlet for fresh air, altogether separate from the window.

The Sheringham ventilator (Fig. 270) is a simple yet cheap and effective apparatus for this purpose. It is an iron box fitted into the wall, near to the ceiling, and communicating directly with the external air. It is provided on the inside with a hopper valve, which may be altogether closed or opened to any desired extent by means of a cord working over pulleys. The valve opens in such a way as to direct the current of air to the roof. The inner opening is larger than the outer, so that the rapidity of the current of air at the outer opening is diminished at the room opening, and the current is spread out as it enters the room. One other advantage of this form of ventilator is that in the event of both outlet and inlet open-

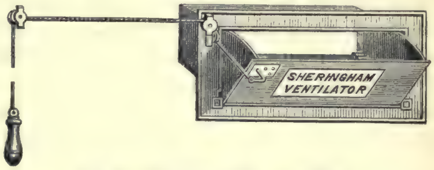

Fig. 270.—Sheringham Patent Ventilator.

ings being provided, it may become an outlet opening, permitting the escape of heated air from the upper part of the room, if fresh air is entering by other channels; and if these other channels are closed, it may again become an inlet opening.

Mr. Pridgin Teale, the surgeon, of Leeds, ventilates his room by means of an opening in the wall near the ceiling, 5 feet by 16, in which is fitted a broad tube. Within this tube is a canvas screen placed diagonally, so that the air is filtered as it passes through, while at the same time the current is slowed and broken up. On the room side he has a Harding's diffuser, an arrangement for spreading out the current into a multitude of tiny streams. The inner opening is also fitted with a door permitting the ventilator to be opened or closed at pleasure. He finds, however, that the arrangement works so well, that it is allowed to remain constantly open, winter and summer.

Another form of inlet ventilator is shown in Fig. 271. It also is fitted into the wall near the ceiling, and communicates directly with the

Fig. 271.—Air Inlet Wall Panel.

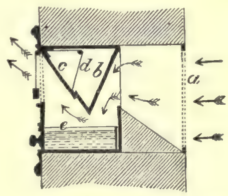

Fig. 272.—Section of Air Inlet Wall Panel.

outside air. A diagram of the arrangement is shown in Fig. 272. At *a* is the opening on the outside by which the air enters; a shield *b* causes the air to be deflected downwards to pass over a trough of water *e* by which the air is cooled, and by which also the air is deprived of a large amount of its solid impurity. The air is then directed upwards towards the ceiling

by the bar in front of the lower part of the inner opening. The valve *c d* is capable of being raised or lowered to regulate the current of air, and the perforated front breaks up the current and diminishes its velocity as it enters the room. Such air-inlet panels may be obtained in many forms, but are all on the same principle. The trough of water may be dispensed with, or it may be filled with some disinfectant, or a filter of gauze may be substituted. A feature of Sheringham's and such ventilators is the ease with which they may be kept clean, a very important matter.

Tobin's Inlet Tubes.—Another method of introducing fresh air is by means of tubes, of a style with which the name of Mr. Tobin, of Leeds, is usually associated. They open directly through the wall on a level with the floor. The tube then rises against the wall to a height above the level of the heads of persons in the room. A regulator is placed in the tube, the handle of which projects at the side, by means

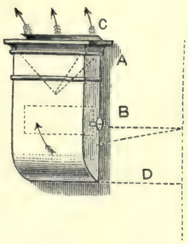

Fig. 273.—Wall Bracket Inlet on Tobin's System.

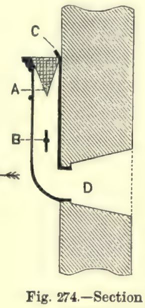

Fig. 274.—Section of Wall Bracket Inlet.

of which the tube can be closed against the current or opened to a greater or less extent. At the opening a projecting lip directs the current upwards and from the wall. In such tubes there is usually a funnel-shaped canvas bag, or similar contrivance, for the purpose of filtering the air. Fig. 273 shows a similar contrivance, in the form of a wall bracket, and Fig. 274 represents it in section. D is the opening in the wall supplied with an outside grating. B is the regulator, A the filter, and C the projecting lip. This bracket would open through the wall above the level of the heads of the inmates of the room. In the case of a tube rising like a pillar or panel in the wall, D would be at the floor line, and the tube would rise inside against the wall as already indicated. These tubes may be made of any ornamental design, as wall pillars, wall panels, wall brackets, &c., so that their real purpose is not apparent, as is evident from Fig. 275. In churches, halls, and very large rooms, pillars supporting beams, galleries, &c., could be utilized for such purposes, the inlet being at the capitals. The difficulty of cleaning such tubes is one of their main disadvantages.

One of these tubes might be employed as an inlet ventilator, and near the ceiling on the op-

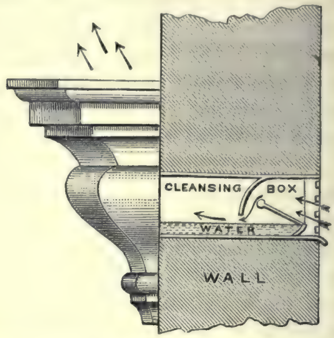

Fig. 275.—Ornamental Wall Bracket Inlet Ventilator, with Arrangement for Purifying the Entering Air.

posite wall, a Sheringham or other similar ventilator might be used as an outlet ventilator for foul air.

Outlet Ventilators.—One situation in which a ventilator for the escape of foul air is frequently placed is in the wall above the fireplace, not far below the cornice. It opens into the chimney, the upward draught causing the ventilator to act. The disadvantage of such a situation is that in the event of a down draught, such as produces back-smoke, smoke from the chimney would be driven through the ventilator into the room. To prevent this, such ventilators are usually supplied with valves of very light material, preferably mica, which close on the slightest stoppage of the upward current.

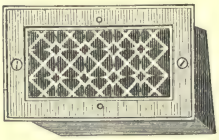

Fig. 276.—Mica-flap Outlet Ventilator (front view).

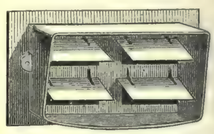

Fig. 277.—Mica-flap Outlet Ventilator (back view).

Fig. 276 gives a front view of such a mica-flap ventilator, and Fig. 277 shows the back view, in which the flaps are seen.

Shaft Ventilators.—In other systems ventilating shafts are used, opening from the ceiling of the space to be ventilated and passing up above the top of the building, such as is diagrammatically represented in Fig. 278. This is the method adopted for large institutions, military hospitals, barracks, &c. When an efficient inlet is also provided difficulties are reduced.

But when there are no special inlets the movements of air in the shafts are much disturbed by the influence of winds, changes of temperature, and so on, which indeed create difficulties

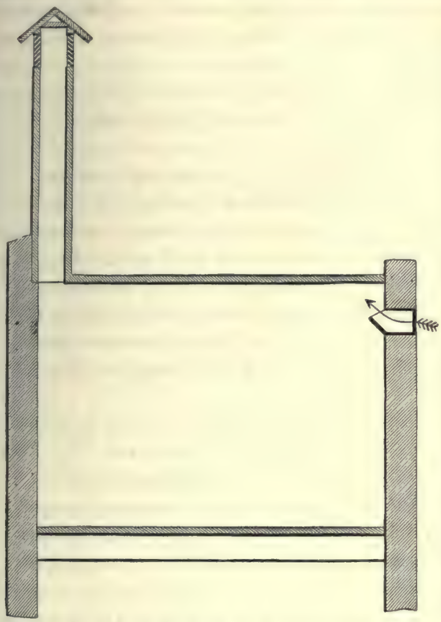

Fig. 278.—Shaft Outlet Ventilator and Sheringham's Inlet Valve.

in every system. But in single shafts there is a tendency to a double current interfering with proper ventilation, one of fresh air passing down and another of foul air escaping, dependent among other circumstances upon the temperature of the space being ventilated, and therefore on the number of persons present in it, and also on the temperature of the shaft.

Watson showed that if a partition completely divides such a shaft into two, a current of fresh air passes down one side and a current of foul air up the other. On this principle M'Kinnell's ventilating shaft is constructed. It consists of two circular tubes, one within the other (Fig. 279), both opening at the ceiling. The inner one rises to a greater height than the outer, and is the outlet tube. The outer or inlet tube is provided with a flange, a little below the ceiling, which directs the entering air along the ceiling and prevents it being poured down on the heads of the inmates of the room or hall. The entering air is somewhat warmed by contact with the inner tube, heated by the escaping foul air. Such shafts need a hood to prevent the descent of rain, and may be provided with cowls turning away from the wind. In such cases the cowl is most efficient when large, with wide projecting mouth.

Shaft systems of ventilation are now usually provided with some arrangement at the head, by means of which the wind may be utilized to exert a suction action for the extraction of the foul air. There are numerous ventilators, designed for such a purpose, in the market. Similar ventilators are sometimes fitted on the roof opening of soil-pipes for the extraction of foul air in the pipe.

The size of the ventilating openings requires to be taken into consideration, and is regulated by the speed which it is desirable the current should possess and the quantity of fresh air to be supplied. This latter, as we have seen, depends upon the number of persons in the space to be ventilated, the number of lights burning, and so on. The production of a movement of air is the result of a difference of temperature. Warm air expands and becomes, therefore, specifically lighter. It therefore rises and is displaced by a volume of cold air flowing in to take its place. The velocity of a current in a chimney or ventilating shaft may be calculated by ascertaining the difference of temperature between the heated and the external air and the height of the chimney. The size of the openings necessary to give a desirable rapidity of current can be calculated out by such data; but as the rapidity will vary with the temperature, so a given size will suit only a definite range of temperature, and therefore the necessity of some means of regulating the size of the opening. The velocity of current at

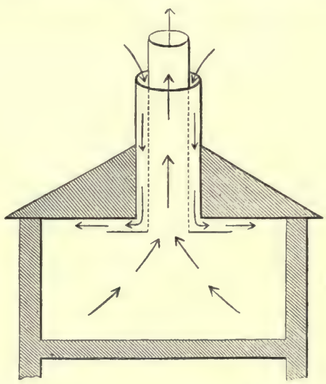

Fig. 279.—M'Kinnell's Ventilating Shaft.

the point of entry of fresh air ought not to exceed, according to De Chaumont, 5 feet per second, and to secure this, "48 square inches of total inlet and outlet area ought to be provided, and this independent of the chimney, if there be an open fireplace." Dr. Parkes says: "It is impossible to fix any size which shall

meet all conditions, even if the influence of wind could be completely excluded, which is impossible. The only way is to adopt a size which will meet most cases, and supply means of altering the size according to circumstances. In this country, a size of 24 square inches per head for inlet, and the same for outlet, seems calculated to meet common conditions; but arrangements should be made for enabling this to be lessened or closed in very cold weather, or if the influence of strong winds is too much felt. Moreover, the size must be in part dependent on the size of the room, because in a small room with many people it is impossible to have the size so great as it would be if each person's space were 48 square inches, unless some portion of the air were warmed. . . . It is desirable to make each individual inlet opening not larger than 48 to 60 square inches in area, or enough for two or three men; and to make the outlet not more than one square foot, or enough for six men. Distribution is more certain with these small openings. It must, however, be borne in mind, that if a calculation is made for a single opening of a certain size, dividing it into a number of smaller openings causes a great loss by increasing the friction. . . . Inlets should not be large and single, but rather numerous and small (from 48 to 60 inches superficial), so that the air may be properly distributed. . . . If there be several they should be, of course, equally distributed through the room, so as to ensure proper mixing of the air."

Ventilation by Chimneys.—It will not be out of place here to note a few practical facts which have been observed regarding the draught produced by chimneys, the chief means of ventilation in many houses. The movement of the air in flues is determined by the differences of temperature of the inside and outside air, as already indicated, and by the length of the flue. Many circumstances, determined by the construction of the chimney, affect the current in it. The movement of the air is retarded by friction against the walls, and, therefore, the more smooth the inner surface is the better will be the draught. Sudden bends, by increasing the friction, diminish the draught. Again, variations in the diameter affect the rapidity of the current, increased diameter slowing it and contractions increasing its speed. Sudden changes in diameter are inadvisable, and whatever change is necessary should be effected gradually, a sudden enlargement having a specially retarding influence on the current by the eddies it creates. A gradual narrowing at the top is quite common and increases the rapidity of the current, while it tends to prevent the descent of cold air; and the throat, or part leading to the fireplace, is also made narrow to aid the velocity there, and prevent the occurrence of a back-draught as well as the escape of unwarmed air into the shaft. Then if several flues enter the one shaft, their direction must be studied. For two currents may meet one another in such a way as almost to destroy the velocity of outflow, and thus make the chimney smoke. All additional flues should, therefore, be made to enter the main shaft as nearly as possible in a vertical direction to prevent such a result. The upper current is also better maintained if the main shaft is somewhat narrowed just below the point of entrance of the additional flue.

A bad draught may be caused by some of the errors in construction indicated. Too wide a flue will occasion it by permitting a current of such diminished velocity that the smoke and air has time to cool, doing away with the difference of temperature which is the cause of any current at all. By permitting the entrance of a large body of unwarmed air, the same effect is produced. A funnel, square in cross section or of the shape of a parallelogram, tends to permit this cooling action to occur; a funnel, circular in section, is best, and in diameter it need not exceed eight inches. If the supply of air to the fire is too little, as it will be when the room is provided with no inlet for fresh air, and when doors and windows are very tight, a bad draught is certain to exist, the remedy for which would be a Sheringham or other form of inlet ventilator. In summer, when no fire is burning in the fireplace, and when the atmosphere of the room is cooler than that of the outside air, the reverse of the ordinary conditions is established and a down-draught is certain. This can be prevented only by valves.

Such faults may be remedied by some form of cap, which makes use of the movement of the wind to produce a suction action, as in the case of Boyle's ventilator or some of the many forms of cowl which move with the wind. A cap is also a protection against the entrance of rain, and against the wind producing a down-draught.

WARMING.

The necessity for the entrance of large quantities of fresh air is almost inseparably associated with that of heating the air, particularly

in climates such as ours. Heat is communicated in three ways, namely, by conduction, by convection, and by radiation.

Conduction of Heat is illustrated in the communication of heat along a poker, one end of which is thrust into the fire. The particles of the poker in the fire pass on the heat, by contact, to the parts outside of the fire, and so the heat travels to the end of the poker. Some substances pass on heat in this way more readily than others; thus metals are all good conductors, some better than others. Wood is not a good conductor, neither is bone nor ivory. Thus in tea-pots made of metal the part of the handle grasped by the hand is usually separated from the main body of the tea-pot by a thin piece of bone or ivory. This prevents the conduction of heat to the handle, which can thus be safely grasped. Air is a bad conductor of heat, so also is water and other liquids, so also are stone, brick, glass, hair, and feathers (see Section V.).

Convection of Heat is the communication of heat by means of the movement of warm particles from one place to another. Thus while a mass of water is not readily heated by conduction, it is quickly heated by convection, that is, currents are quickly set up in the water by which the heat is distributed through the whole mass. When water is being heated in a kettle, as soon as the layer of water touching the bottom of the kettle is warmed by contact, it rises through the cold layers above, and cold water flows in to take its place. This becomes heated and in turn rises, so that the convection currents, set up in the water, speedily cause the whole quantity of water to be warmed. This is specially the way in which heat is communicated by air, which is, as we have said, a bad conductor. No sooner is one portion of air heated than a current is produced, the heated air rises, cold air flows in to take its place, and so the heat is distributed.

Radiation of Heat is not so easily understood. It is independent of air. It is because of radiation of heat from the sun that one is warmed when walking exposed to its direct beams. On a winter's day, when the frost is keen, if the sun is shining brightly upon us, we feel warmed by the rays. The heat we feel is not communicated to us by means of the air, for as soon as we fail to receive the direct rays, as by walking into the shade, we feel again only the keenly cold air. If it had been through the medium of the air that the sun's heat was communicated to us, we would have felt it equally warm in the shade as in the sunshine, for we are surrounded by the same air. Nay if, without moving from the spot where we feel the pleasant warmth poured upon us, the finest possible shield be interposed between us and the direct rays of the sun, if it be only a screen of tissue-paper, we feel at once the same sensation we experienced in passing into the shade. The heat is not communicated to us by the air, for even while we are enjoying the sun's warmth the thermometer may indicate the temperature of the air to be below the freezing point. The heat, then, from the sun is reaching us through the air, but its rays pass through the air without perceptibly warming it. It is only when the heat-rays fall upon a body capable of absorbing them that the body becomes warm. The air does not readily absorb heat; it allows the heat-rays to pass—that is to say, it transmits the heat—but it does not absorb it; but as soon as the heat-rays fall upon our bodies we absorb them and thus feel the warmth.

Open Fireplace or Heated Air.—Now we have stated at this length these methods of communicating heat, because they explain a great difference between sundry systems of warming. For example, if we compare the method of heating an apartment by the ordinary open fireplace with that by driving into it air previously heated, or heated in the apartment itself by hot water or steam pipes, the broad contrast will be readily shown. In the case of the open fireplace the heat is communicated to the apartment by radiation, not by heating the air. The radiant heat from the bright fire passes through the air without perceptibly warming it, and falls upon the walls, chairs, and other furniture, warming them. If a person be sitting within range of these rays he receives them and is also warmed. It is a quite familiar fact that if on a very cold night a person be sitting sideways to the fire, the side of the body towards the fire is unduly warm, while the other side of the body may be feeling half-frozen. It is plain this could not happen if the heat was communicated by the air of the room. It is due to the fact that the radiant heat from the fire is falling on one side and not on the other. Well, then, the walls, furniture, &c., of the room are warmed by the radiant heat, the air of the room not being directly heated at all. The air of the room does, however, become subsequently heated by convection currents. The air in contact with the warm walls, furniture, &c., becomes warmed, rises, and so currents are produced, colder air coming into contact with the walls, &c., and being in

turn warmed, so that by and by the atmosphere of the room becomes warmer, *but it is always less warm than the inclosing walls, furniture, &c.* Moreover, the burning fire demands a large supply of fresh air, which it will draw for itself from every available crevice leading to the outside of the room, and thus the air is continually renewed and its warmth diminished. On the other hand, when air is warmed by some apparatus and admitted to the room, there is no radiant heat, and one breathes warm air. If the heating be accomplished by hot air or steam pipes in the room, or by such contrivances as the German stove, it is again by heating the air that warmth is communicated. Heat does radiate to some extent from the hot pipes and the stove, but the heat is chiefly distributed by the air becoming warmed by contact with the hot pipes, and convection currents being thus produced. Moreover, the absence of the open fireplace does away with the guarantee of a certain amount of ventilation constantly going on, and in the absence of a very efficient system of ventilation by special inlet and outlet openings, the evils of bad air are added to the disadvantage of rarefied air, the disadvantage of a deficient quantity of oxygen with every breath inspired. These are the causes of the languor, want of freshness, feeling of oppression, and headache so common in halls or rooms heated by means of hot pipes, and not provided with a very efficient system of ventilation.

At the same time in cold climates there is almost a necessity for some arrangement for warming to some extent the large volume of air required for efficient ventilation. That is to say, while the open fire is the most desirable and simple means of warming rooms of ordinary size and small halls, it is frequently scarcely sufficient in cold raw climates, or at cold seasons of the year, and various methods have been suggested for supplementing it.

The Construction of Grates.—The ordinary grate, however, is not constructed to produce the full effect the open fire is capable of. As already indicated, it warms a room by radiation, but the ordinary grate is not usually constructed to permit radiation to take place to the fullest possible extent. There are various reasons for this, some of which may be stated. First, the coal is not completely burned. The air does not gain access to the fire in such a way as to produce perfect combustion, not necessarily because of an insufficient supply of air, but because of a bad distribution through the burning mass. Much material, in the shape of soot, smoke, and gases, escapes up the chimney, which would have given off a great deal of heat had complete union with the oxygen of the air been effected. Then, according to General Morin, five-eighths of the heat are not utilized in heating the room, but are lost up the chimney. The material of which the fireplace is made is often not the best for radiating heat into the room, and its shape is not adapted for such a purpose, for example the old large square fireplaces. It was Count Rumford who, in 1796, pointed out the waste of the heating capacity of the fuel which the style of grate then in use occasioned. He brought the grate to the front of the hearth recess, reduced the width of the back of the grate to one-third of that of the recess, and built the back and sides of the grate of non-conducting material, such as brick or fire-clay. An important alteration was that by which the sides of the grate were made to slope outwards from the back, so that when they became hot they radiated their heat into the room. The wide throat of the old chimney was narrowed, so as to diminish the total volume of air drawn into the chimney by which the fireplace was continually being cooled down, and which also secured more complete combustion of the coals. These are the general principles which ought still to guide the construction of fireplaces. Glazed tiles may be used for the back and sides, as they emit the heat more rapidly than unglazed. A fire-brick slab sloping slightly upwards from the back assists the radiation of heat and the combustion of the fuel. Many grates of modern construction are provided with special arrangements to prevent all the cold air entering directly. Part is led from below up flutings on the back, and in other ways, to be delivered partly warmed into the heart of the fire, to ensure complete combustion. Such improved grates also economize fuel.

Teale's "Economizer."—Mr. Pridgin Teale has suggested a very simple arrangement which he maintains effects more complete combustion, causes more heat to be given out to the room, and saves fuel. It has the advantage of being very cheap, and capable of being applied to any form of grate. He removes the ash-pan from under the grate, and incloses that space by an iron plate of a shape to fit the grate, resting on the hearth and rising as high as the bottom bar of the grate. The space below the grate thus becomes a closed chamber; air is not permitted to enter the fire from below at all, and the draught is thus diminished and slower combustion secured. The coal, however, is more com-

pletely burned, for since no cold air enters from below, the bottom layer of coal is kept very hot, so that the cinders become consumed, and the fine ash produced drops through the bottom into the inclosed air space. Then the inclosed air space is a hot-air chamber, giving out considerable heat and maintaining a uniform rate of combustion. The iron shield Mr. Teale calls, on this account, the "Economizer."

All the contrivances noted, however, are simply devices for utilizing to the utmost the radiating power of the open fireplace.

It should be observed further that the heat given out from the open fireplace would be of much greater value for heating an apartment if the fireplace were situated not in an outside wall, owing to which much heat is lost, but in an inside wall. The heat, which, in the former case, is lost by being passed through the wall and given off to the external atmosphere, would, in the latter case, be wholly utilized in warming the atmosphere of the house. This, of course, implies economy in fuel.

The Galton Grate.—We must now refer to a method by which the open fireplace is made use of also to warm the fresh air entering the room for ventilation. The air so warmed should not be heated above 54° to 60° Fahr. By such a contrivance the advantages of the open fireplace are retained and the disadvantages of admitting large volumes of very cold air to the room got rid of. The grate called the "Galton Grate," devised by Captain Galton of the Royal Engineers nearly thirty years ago, is the example of such an arrangement. Behind the grate is a chamber into which pure air from the outside is admitted. The back of the grate is provided with a set of gills, in passing over which the pure air is warmed. This air then passes upwards by a flue alongside of the chimney and enters the room above the fireplace. This chamber and flue are altogether shut off from the grate and chimney and obtain their air from the outside only. There are now many forms of such open fireplaces.

The warmed air entering the room above the chimney-piece is caught by a current passing upwards to the roof in front of the fireplace, and is thus broken up near the ceiling into various currents, so that it is rapidly distributed through the apartment.

Stoves, and specially **Slow-combustion Stoves,** are now being largely employed, in particular for the heating of halls, &c. They may be made of iron or glazed earthenware. The latter is a worse conductor of heat than the former, but it in consequence parts with its heat more slowly and regularly, so that a uniform temperature is more surely maintained by an earthenware or brick stove. The value of such stoves from an economical point of view is due to their internal arrangements. The smoke and gases given off from the burning coal are conducted upwards and downwards within the body of the stove before they are allowed to escape by the chimney, and thus they are caused to part with the main portion of their heat to the material of the stove, which in turn gives it off to the air of the apartment. Then, once the fire has been lighted, the doors are closed, and the air supplied very slowly, so that one charge of fuel will last from morning to night; the heat will be slowly given off, and utilized to the greatest possible extent. Such contrivances, therefore, create no draught of any value for ventilation, while their value for heating purposes being dependent upon the warming of the air, and not on radiant heat, doors and windows are usually kept closed to get the full effect from them. They are, therefore, likely directly to create the temptation to inefficient ventilation. Such stoves are in constant use in Germany for warming purposes, no open fireplaces being used; hence the designation **German Stoves.** Any one who has only experience of their use for warming the atmosphere of a whole house, the stove being in the hall, will not realize their disadvantages to the same extent as one does who has experience of their employment abroad in the living- and sleeping-rooms. When the fire is charged in the afternoon, the doors and windows of the bed-room are carefully closed, and when one enters the room for the night, the atmosphere feels stifling and is almost unendurable. One instinctively rushes to open the window for a draught of fresh air. There is, however, a modification of such stoves by which a pipe carrying fresh air from the outside may be passed through a part of the stove, and allowed to escape at the top into the room, so that a supply of fresh warmed air is obtained. But this implies a larger consumption of fuel, a more rapid combustion in the stove, else heat would not be produced sufficient to warm to any degree the fresh air passed in.

Gas Stoves.—Wherever gas stoves are used it is necessary to ensure that the products of combustion are passed off to the outside and not permitted to escape into the apartment. The gas ranges, now so commonly used for cooking purposes, err in this respect. The lower part of the range, occupied by the oven, is provided

with a flue, by which the products of combustion are conveyed to the outside, but the various gas jets, arranged in ring form &c. just under the grating of the top of the range, give off all the burnt gases into the apartment, and the smell is perceptible immediately after the gas has been lighted. If a gas stove is fitted into the ordinary grate recess, so that all the combustion products escape up the chimney in the ordinary way, the objection is removed; but usually the gas range stands out into the floor at the side of the ordinary grate, in addition to which, or instead of which, it is being employed. This is decidedly objectionable. It is now also common to see an ordinary range adapted for gas, at least to some extent. The oven may be heated by gas, and on the hot plate above the oven, it is also becoming quite usual to fit ring-jets on which a kettle, pot &c. could be boiled. In this way no evil is incurred, for the burnt gases escape up the chimney as the smoke from the ordinary fire. Some of the gas stoves adapted exclusively for warming purposes also exhibit the fault of discharging their burnt gases into the apartment, and these are not to be recommended. Only those should be selected which are provided with a flue; and there are now many forms which can quite easily be fitted into the fireplace of the ordinary grate, discharging their waste up the chimney. Gas stoves of whatever form are not economical, for continuous burning, at the present price of gas. Asbestos stoves heated to redness by gas are so arranged as to give out a large amount of radiant heat, but they are only economical owing to the fact that they can be put out at any moment and relighted with equal rapidity. They are expensive if used for any time on end. If they are used only now and again, for a short period, then they may be more economical than coal, and they save an enormous amount of labour and dirt.

Gas, however, is now being employed for warming the fresh air admitted to a room for ventilation, and may be combined with modifications of inlet tubes such as have been described, and with an open fireplace. Fig. 280 is an illustration of an air inlet tube A, in the interior of which is a small chamber C provided with a gas jet D. This chamber is continued into a pipe B coiling through the compartment, through which pass the heated products of combustion. This pipe may end in a chamber G open to the outside by H, but shut off from the space of the inlet tube, and containing some material for absorbing the waste gases that escape; or the pipe may be carried up the inlet tube J, again to pass out above. The gas jet is supplied with air for its combustion through the openings E and F. Air enters the space of the inlet tube, and is warmed as it passes through it by contact with the coiled pipe. It may be filtered before passing into the room by the conical canvas bag shown. The entering air is admitted through an opening guarded by a shutter, K, which is raised or lowered to any desired extent by the cord passing over the pulley L, and counterpoised by the weight, M.

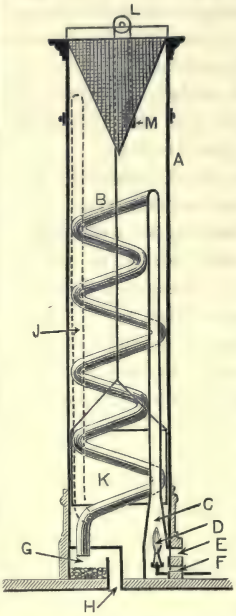

Fig. 280.—Air Inlet Tube fitted with Fresh Air Warming Arrangement (Boyle).

In concluding these paragraphs on the very difficult subject of ventilation and warming, the author does not wish to ignore the fact that the review of some of the chief methods now adopted for introducing an abundant supply of fresh air into apartments without unduly lowering the temperature, while it may be very valuable to the man who wishes to build his own house or already owns one, may not afford much aid to those who are simply tenants and have neither the means nor the opportunity of adopting any of the more elaborate systems. They may wish at the same time, and may be able to adopt, some simple and inexpensive method, as far as possible to achieve the ends desired. To such it may be said, that if they will give themselves a little trouble in the securing of grates which are constructed to give out the greatest amount of heat, and which are now almost as readily obtained as those of bad construction, and if, in addition, they can fit up such an inlet regulating ventilator as Sheringham's or others of like construction, or Teale's, they will do much to accomplish what is required.

HOUSE DRAINAGE.

The Nature of Waste from Dwellings.—In this section we have to consider various methods for the removal of waste from dwellings. What is the nature of that waste? It is partly liquid and partly solid. The liquid portion consists of waste water from baths, sinks, wash-hand basins &c., and we may also add rain-water caught on the roof and led off by pipes. In all this there is both animal and vegetable matter, capable under certain conditions of temperature of undergoing rapid decomposition and giving off putrefactive gases. There remains to be added the urine voided from the bodies of the inmates of the house, which very speedily decomposes. The solid portions of the waste consist of refuse of food, both animal and vegetable, dust, ashes &c., and the solid waste passed off from the bowels of the inmates. In primitive conditions, and in places where the population is sparse, there is no great difficulty in suitably disposing of such waste. The organic material, both animal and vegetable, which such waste contains, in ordinary course undergoes decomposition or putrefaction. This, as has been pointed out at length in Section XIII., Part I., is the process by which complex bodies are broken down into simple bodies or elementary substances, in which form they are again useful for the nourishment of plants, in which form, also, they are harmless. Thus the urine contains urea, the waste of nitrogenous foods consumed in the body. If it be exposed for a time to the air we know it becomes offensively ammoniacal in smell, because the urea has become transformed into carbonate of ammonia, and if it be thrown upon the soil the nitrogen it contains is available for the life and growth of the plant. So it is with the other organic substances. This process of breaking down, of reduction to simple, inoffensive, useful, substances, is accomplished chiefly by the agency of the oxygen of the air; it is essentially a process of combustion, of oxidation, of burning, and it cannot be accomplished unless there is free exposure to air, or free exposure, under suitable conditions, to substances which will yield the needed oxygen in suitable quantity. If the waste be freely exposed to the open air, this process of oxidation will in good time be accomplished, and then the waste becomes valuable for scattering over fields, and so on, to enrich the soil. Suppose the waste in its fresh state be scattered over the soil, it is freely exposed to the air, the liquid portion which sinks into the soil, meets the air in the soil, the ground air, and gets the necessary oxygen. This distribution

over the soil can, however, be accomplished only during certain periods of the year, and it may be, therefore, necessary to accumulate it in heaps till the period when it can be used. This also may be done without harm, if the accumulation be made at a proper distance from the dwelling. If the waste be cast into a stream, it is rapidly carried off. In the water it also undergoes combustion, not because of the water itself, but by the agency of the oxygen, dissolved in the water to the extent of something like 2½ cubic inches to the gallon. In time no sewage, as such, will be found in the stream; it has all undergone oxidation. Where the population is sparse, then, the resources of nature are quite sufficient to deal with the waste from human habitations. As men congregate, however, the circumstances are changed. The bulk of waste becomes too great for the natural resources of the place to cope with. It becomes necessary to make arrangements for its removal to great distances. If it be cast into a stream, the current may be sufficient to carry it rapidly away, but then the stream is seriously polluted, and if no great distance separates the place where the waste enters from another, lower down the stream, where other dwellings exist, there is no time for natural purification to occur. The magnitude of the difficulty becomes enormous when the waste of a town has to be dealt with. A few figures will show this clearly. If we consider simply the waste cast off from the human body, 40 ounces per day of urine and 2½ ounces per day of solid excrement per head is a low average for both sexes and all ages. This makes, for a population of 1000 persons, 260 gallons of urine and 156 pounds of solids per day, or 91,250 gallons of urine and 25 tons of solid excrement per year. If there be added to this waste water of all kinds and solid refuse, the amount to be disposed of becomes enormous. In order to simplify our consideration of the question, we shall begin by considering the disposal of the human waste, or excreta (from Latin *excerno*, to separate out), along with waste water. It is necessary to provide channels for waste or slop water from houses, at any rate, and we shall consider that human excreta both liquid and solid, are cast into the same channels to be carried off in the same way. We can consider later other methods proposed for dealing with solid human excrement, as well as the means of disposing of the other solid refuse of the dwelling.

This system of casting into the same channel waste water from the dwelling as well as human excreta is common, because the water carriage thus provided is an easy method of removing the solid excrement. It is efficient also and not expensive. The channels may ultimately be made to discharge their contents into a river or into the sea, or into tanks where the collected material may undergo some purification by chemical means, to be afterwards disposed of in some convenient way, or it may be collected into reservoirs and thence distributed over soil for manurial purposes.

Disposal of Waste.—Our present concern is its speedy removal from the dwelling. This is apparently simple enough. To the sink, wash-hand basin, water-closet &c., a pipe is connected. These pipes join one another and form a common pipe leading out of the house, or they are branches of a common pipe, passing through and ultimately leaving the house. Into this same main pipe pass pipes collecting the rain-water from the roof. The rain-water pipe may pass down one side of the house, then below the basement to join the main pipe at the other side. Thus rain-water from the roof, waste water from bath-rooms, dressing-rooms, kitchens, and sculleries, and excreta from water-closets all enter one common pipe either within the house, or the pipes, which they enter, ultimately join one common pipe outside the house. Moreover the pipe from one house or one tenement joins that from another house or tenement, the common pipe being now enlarged for the purpose, and as this passes onwards it receives additions and branches from other houses &c., becoming larger as it proceeds and carrying ever-increasing quantities of waste. The pipes inside the house are called **drains**, and the same term is applied to the main pipes leading from the house or tenement, but the larger pipes or channels into which the drains from several houses pass are called **sewers** or **common sewers**. The sewers pass on until they open let us say into the river, into which they discharge their contents.

Now let us consider what this apparently simple system means. The material in the drains and sewers is covered up, excluded from the air, until it is discharged into the river. It may have to pass through miles of piping before its exit. Air is present in the drains and sewers to some extent and also in the water, and thus some amount of oxidation can occur, but the oxygen obtainable is a mere fraction of what is necessary, and thus the natural process of reduction of the organic substances to simple and harmless elementary bodies cannot occur Meanwhile, however, putrefaction is not pre-

vented, decomposition proceeds to some extent, and putrid gases and all the noxious effluvia capable of being given off from such mixed ingredients fill the pipes. If the connection of the house drains with the sewers is the simple one indicated, it is plain that there is no barrier to the passage of the sewer gas into the house. The waste as it enters the house drains is not yet in a state of putrefaction and it is carried rapidly away by the water, so that thus far no harm can arise. But the atmosphere of the house is in direct communication with the atmosphere of the drains and sewers, and that of the house being warmer, there is an actual suction exerted upon the sewer gas, drawing it into the house. Moreover that is not all. Such a simple means of connection implies that the atmosphere of one house is in direct communication with another through the drain-pipes, which are a sort of secret subterranean passage, and a man who is scrupulous about having fresh air in his own house may yet enjoy the foul air of his neighbours through this unsuspected means of communication.

Cesspools.—When it was not possible to lead the sewage off by a stream it used to be the practice, and indeed in a restricted sense is so still, to build a cesspool, into which the drains from the house were carried. These cesspools were built of brick or other porous material, and allowed the liquid portion of the material to ooze into the ground, the solids being retained. When the cesspool was full, the retained solids were available as manure for field or garden purposes. Even where the drains of the house were connected with a general sewerage system for removing the sewage, cesspools were interposed before the drains joined the sewers for the interception of the solid portions, the liquid parts being provided with an overflow into the sewers. It was not even customary to empty the cesspool when full, unless there were obvious advantages by doing so in the securing of manure, but, to save trouble, when one cesspool was full a new one was dug, and the sewage conducted into it, the old one being simply covered over. Not only was this usual in country districts and at a distance from the house, but it was also common in towns, for example, in London, and the cesspool was actually dug in the ground covered by the house itself, all the sewage from the house being conducted into it. When one was full, a new one was dug. Thus the late Mr. Eassie writes: "Many of these cesspools are to be found in the older houses of London in the basement, and oftentimes under the kitchen floor. . . . The custom was that when one cesspool was full another should be made, and thus a great many of these receptacles are discovered in one house. . . . It is not uncommon to find cases where the house was built first, and, for want of a suitable fall, the cesspool dug out inside the house. This was the case especially in large mansions with ample cellarage room, and I have discovered and removed as many as eighteen cesspools in one mansion. . . . On one occasion I laid bare five of them, just outside the walls of a residence, and they averaged forty feet in depth! . . . There are in London yet thousands of houses which drain into cesspools, and have only the overflows taken into the sewer. As a matter of course all these cesspools should be abolished, and when a block of old houses is pulled down in a city like London, the whole site should be ploughed up in a search for these old receptacles, as otherwise some of them may come to be left inside the walls of the new house."

Under no circumstances ought cesspools be allowed to exist in towns or where there are numerous houses in immediate proximity to one another. In the country they may be unavoidable; but if so they ought to be so constructed and situated as to do away with the risks attendant upon them in ordinary circumstances. Suppose a country house built upon a slope, and the sewage carried to a cesspool at some distance down the slope, and this at a considerable distance not only from the house but below the house level, and suppose that still below this there spread out fields under cultivation, then it will be admitted that, provided the house pipes are properly disconnected from the cesspool, as described on p. 709, no harm can possibly arise from the cesspool being built of porous material and permitting the sewage to ooze through it into the field below, where it will enrich the soil and fertilize the crops. If, however, at any subsequent period these fields should come to be feued for villas or other dwellings, the sewage filtering down on them from behind could no longer be tolerated. Where, however, there is no proper fall the cesspool must be water-tight, else the escaping fluid permeating the soil would reach the foundations of the house, allowing unhealthy emanations to reach the dwelling, unless the cesspool were at a great distance. It might also gain access to the water supply and pollute it, almost certainly if the water were obtained from a neighbouring well. The cesspool should then be water-tight, it should be

properly ventilated, and the inlet pipe should deliver the sewage through a disconnecting arrangement, to ensure the impossibility of sewage gas passing up the drains to the house. It is deemed also best to lead the sewage through some straining tank, which will permit only the liquid sewage to pass to the cesspool. In such a case the intercepted solids should be collected daily and mixed with earth and perhaps some material to remove smells, and then made use of for manurial purposes. The liquids collected in the tanks would require either to be at regular intervals pumped out and carried away, or some arrangement might be adopted whereby the liquid could be led away into pipes and used for irrigating purposes, the pipes starting from the cesspool being for some distance of glazed earthenware, passing into ordinary agricultural pipes.

Dangers of Sewage Gas.—To return, however, to what we have described as the apparently simple and easy method of removing sewage from a dwelling by pipes in direct communication with the interior of the dwelling. What are the evils of such a system? Let us suppose also that these pipes are directly connected with a cesspool either inside or outside the house. In such circumstances, as already said, sewage gas inevitably gains access to the dwelling. What is the nature of this sewage gas? It contains the ingredients of common air, oxygen, nitrogen and carbonic acid gas, the oxygen in less proportion and the carbonic acid gas in greater proportion than ordinary atmospheric air. It also contains gases from the decomposing sewage, marsh-gas or carburetted hydrogen, sulphuretted hydrogen in small quantity, that horribly fetid gas which gives the smell to rotten eggs, and ammoniacal vapours. The quantity of these noxious gases varies with the construction of the drains and sewers and with the amount of ventilation provided for them. Where the ventilation is good these gases may exist in extremely minute quantity, scarcely appreciable. But there is besides fetid organic matter in the sewer gas, whose character has not been precisely determined, but which imparts to the sewer gas its specially hurtful property to health. Even when such fetid organic matters are in such minute quantity as not to be detected by the senses they are yet capable of doing much harm to persons breathing for any time the atmosphere contaminated by them. Let us now ask what effects does such sewer gas produce upon the body. Can emanations from drains occasion typhoid fever, diphtheria, cholera, blood-poisoning, as is so often alleged? This question would be answered in different ways by different people. I shall endeavour to answer it in a way consistent with recent discoveries regarding the causes of these special diseases. If we are to accept as true the modern investigations regarding germs and their part in the production of disease, and everyone accepts them as true, then scarlet fever, measles, diphtheria, typhoid fever, cholera &c. must be held to be the result of the activity within the body of the particular germs of the particular disease, introduced from without, just as a crop of barley, corn, &c. can only be produced from a soil in which their seeds have been sown. Further, just as "men do not gather grapes of thorns, nor figs of thistles," so it has never yet been found that the germs or seeds of one disease can by any peculiarity of circumstance produce another disease. Measles cannot "pass into" scarlet fever nor scarlet fever into diphtheria. If a patient recovering from scarlet fever is attacked by diphtheria, we can only conclude that he has received into his body not only the seeds of scarlet fever, but also the seeds of diphtheria, however impossible it may be to discover how they have reached him. Moreover if a person is attacked by measles &c. we are compelled to conclude that the germs or seeds of measles have gained entrance to his body, just as if potatoes or corn spring up in a field we say the seed must have got into the soil, whether anyone has been known to sow it or not. To say that a child caught cold, and it "turned into" diphtheria is, according to modern science, as absurd as it would be to say snow fell on a field and from it there sprang up turnips. This being understood let us, in the first place, suppose that a group of houses drain into a common sewer, and that into that sewer there has been discharged only the ordinary simple excreta of the dwellings, no disease being in the houses and, therefore, no excreta containing disease germs of any kind gaining entrance to the drains. Suppose these drains are so constructed that sewer gas from them passes into every one of the houses, what evils may it do? Let us suppose that the inmates of the houses are all, to start with, in the enjoyment of excellent health, living regular lives, with good food, good water supply, uncontaminated, and with plenty of outdoor life and exercise. Then they may live for years in the houses and finally leave it for some other abode entirely unaware of the unhealthy condition in which it actually is. The natural healthy body, that is to say, has a well-marked

resisting power to unhealthy conditions. But if any of the inmates are debarred from going out for prolonged periods, then the constant living in the contaminated atmosphere is likely enough to tell, almost certainly will tell, sooner or later, though perhaps only in vague ways. It is commonly the women, whose duties keep them at home, and not the men, whose business continually takes them out of the house, who show the first indications of any insanitary condition. But in particular children are readily affected, and specially young children. They have much less resisting power; and young children, not yet of school age, are so apt, because of weather conditions, to be shut up for many days at a time in the house that they are often the first to appear to be not in a satisfactory state of health. So that it is in wet weather signs of disease are likely to appear, and in cold weather when doors and windows are kept shut and there is less communication with the pure air of the outside. When, however, the insanitary condition of the house asserts itself it will not be by the appearance of a specific disease, such as diphtheria, typhoid fever &c., for we have assumed that there is no way by which the germs of such diseases could enter the drains. Let it be observed that we do not say such diseases may not appear in any of the households, we only say such diseases cannot arise *from the sewer gas* which is gaining entrance to the house. If such diseases do appear it is because they have been communicated in some other way, by infection from some person who has suffered from the disease or has been in its immediate neighbourhood. Further let it be noticed that persons living in a badly-drained house are all the more apt to fall victims to any of these specific diseases they may meet outside, because the frequent breathing of the sewage-tainted air has diminished their resistance to disease. *In short the emanations from simple sewage cannot produce a specific disease, but they can act injuriously upon the general health of the inmates of the houses producing disorder and disturbance of a variety of kinds, to be noted immediately, and diminishing the natural disease-resisting power of the healthy body, so that the person is a fit subject for taking any disease he may be exposed to; and they act thus most particularly upon any inmates of the house who have little outdoor exercise such as women and young children.* In another way also the sewage-tainted air may prove greatly injurious. If one of the inmates has been seized with illness, has caught, for example, a severe cold, or has been seized with inflammation of the lungs, then his general vigour is reduced, the foul air has its opportunity, and seriously delays and impairs his recovery. Or again the wife is confined of a child in the house, and her recovery is neither so speedy nor so satisfactory as everyone had expected. Her resistance to unhealthy conditions is diminished and so the foul air has its full effect upon her. In all these vague, ill-defined, ill-understood, and unsuspected, ways are sewage emanations daily, aye hourly, affecting the health, the vigour, the life, of large masses of the people, specially in large towns, and there are few who think of it, fewer who know of it, and many who laugh at the notion of it. Yet the author could give instance after instance, from his own experience, in which the operation of the sewage gas has been made out as conclusively as a mathematical demonstration.

But simple sewage emanations may do more than this. They not only diminish disease-resisting power by lowering the vigour of the general system, they not only take advantage of a general system lowered by other causes, but they produce actual diseases, *though of a non-specific character*, and specially, as already said, in those most exposed for long periods to their influence. In adults the symptoms are often only those of a general *malaise*, of a general state of ill-health, such as want of appetite, bad digestion, headache, pallor &c. Frequent sore-throat, sickness and vomiting are common. Marked disorder of the stomach and bowels, purging and diarrhœa, are also consequences. In children very marked symptoms are frequent, such as severe sickness, and vomiting and high fever are quite common, as well as less-defined symptoms of general ill-health, decline of vigour, and so on.

In the next place let us suppose that the sewage is not of the simple kind we have at first assumed. We shall take it for granted that in a house connected with a system of drains, in direct communication with all the other houses discharging into the system, there are one or more cases of some specific disease, such as scarlet fever, diphtheria or typhoid fever, or that there are cases of several of these diseases in different houses of the system. Then the excreta of these patients are cast into the drains. Into the sewage there gain entrance the germs or seeds of these diseases, some of which may multiply there. If the drains are not properly flushed, or if there is a block anywhere, the sewage may become charged with the germs, and it is at least possible that by the bursting of bubbles

of gas, produced by decomposition, germs may become disseminated in the sewer air, and may be drawn into the houses connected with the drains. If the drains are badly laid or the sewers are badly constructed, leakage will take place into the soil, and if the water supply be drawn from wells in the neighbourhood, the water will almost certainly become contaminated and an epidemic is nearly a certainty. Diarrhœa, dysentery, typhoid fever and cholera have thus been propagated. But that these diseases can be propagated by the sewer gas alone, in such circumstances, seems from numerous experiences almost certain. At the very least the risk is enormous. Besides the diseases named diphtheria and a form of inflammation of the lungs (epidemic pneumonia) have been traced to such polluted air. In 1888 an epidemic broke out in an industrial institution in Glasgow in which over 60 boys were attacked, four dying after a few hours' illness. A form of inflammation of the lungs was characteristic of this epidemic. Careful investigation laid the blame on the sanitary arrangements. The institution was in the immediate neighbourhood of an old burial-ground, effluvia from the soil and from the drains gained access to the building, and school-rooms and dormitories were not supplied with pure air sufficient for the number of inmates. The conclusion seemed irresistible that these conditions were the cause of the outbreak. Many more illustrations could be given of a similar kind. Instances are numerous where the opening of blocked drains, old cesspools, &c., has been attended by epidemic fevers, with fatal results.

Sewage gas, pure and simple, is then injurious to health and productive of disease, how enormously is the danger increased from emanations from sewers, into which discharges from multitudes of houses, including the excreta from probably a great variety of diseases, are poured? It is absolutely necessary, then, that some means be provided which, while permitting the free and rapid escape of waste from dwellings into drains and sewers, shall effectually guard against the possibility of foul air from the drains and sewers gaining access to the houses. For this purpose two means are adopted, one seeks by the use of appliances called traps to intercept the backward passage of sewage gas, and the other seeks by ventilating the drain-pipes to have the air within them constantly as pure and fresh as possible. We shall now describe in detail the different appliances and their method of application.

Traps. The simplest form of trap is the **syphon**, shown in Fig. 281. It is a simple dip in the pipe, the effect of which is to retain a quantity of water which acts as a seal preventing the backward passage of air from the drain into the house. There are possible objections to this kind of trap. If it is shallow it may readily

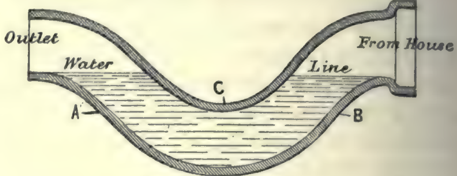

Fig. 281.—Syphon Trap.

be rendered useless. For it is to be noticed that the effective barrier to the passage of gas is the layer of water above the line A B. If, by evaporation or otherwise, the water fall to the level of the lowest part of the bend C, that is, the level indicated by the line at B, the slightest further diminution of water will open a way for the gas from the outlet side through the bend to the house. This might happen if the bend were shallow and the trap small. Further if the pipe be a small one the water in the trap may be syphoned off. If the drain below the trap be running full the suction action exerted by the mass of running water may draw the water from the trap and leave it wholly or partially empty, so that there would be no longer any obstacle to the backward passage of gas. These evils are overcome by ventilating the trap as explained further on. But suppose some obstruction to the outflow further down the drain causing some retention of sewage and the development of a large quantity of gas, the pressure of gas might so increase on the outlet

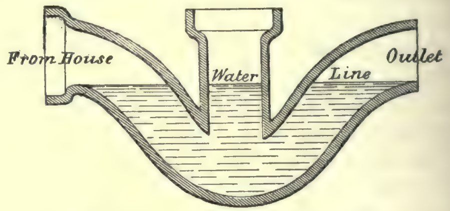

Fig. 282.—Common Lying Trap or Access Syphon.

side as to impregnate the water, and perhaps cause the gas to bubble through the water and so escape into the house. This is also met by ventilating the trap, as shown in Fig. 283.

The **access syphon** is shown in one form in Fig. 282. The additional pipe is let into the centre of the bend. If it comes up to the level of the surface the top may be covered with

a grating and then it acts as a ventilator. It is usually simply covered with a slab of stone and is then used for an inspection or cleaning "eye," permitting in such a case no ventilation. It is, however, not a very good kind to employ. Its position is such that floating excreta are apt to be retained in the added tube, not being swept out by flushing water, and undergoing there decomposition.

Ventilating Trap.—A form of ventilating trap is shown in Fig. 283, where A is the inlet pipe from the house, B is the outlet to the drain, the two being cut off from one another

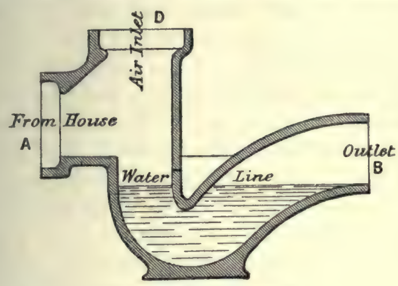

Fig. 283.—Ventilating Trap.

by the trapping water. The ventilating shaft opens at D, and is fitted with a grating. This is the general form of trap for use outside a house. It practically cuts off the house-pipes altogether from the outside drains, the air-chamber disconnecting the two systems. This trap is, therefore, also called a **disconnecting** trap. It is placed outside the house on the soil-pipe drain at a little distance from the house. If it cannot be taken any distance from the house wall, care should at least be exercised that the grating is not in the immediate neighbourhood of a door or window, else a smell will certainly be felt from it, and be occasionally wafted into the house. Fig. 284 shows a similar trap (Buchan's) with an additional opening D for access for cleaning purposes. The cover of D should be fixed down with mortar, and a small brick chamber built up to the ground level, covered with a slab, so that access can be had. Note that by mistake this opening D is sometimes made the ventilating opening, and is covered by a grating. It ought not to be so. C is the opening to be covered by a grating. With such an arrangement, supposing the waste water from baths, sinks &c. as well as rain-water from the roof, to be carried off by a pipe, separate from the soil-pipe, such a pipe could discharge in the open air, over the grating of the ventilating trap. Thus neither the soil nor waste-pipes could be the means of carrying sewage gas backwards into the house. It is not desirable, however, that soil, waste and rain water should pass through the same ventilating trap in the immediate proximity of the house. The soil-pipe should be separate altogether from the waste and rain-water pipes, and these latter should be cut off from the soil-pipe drain by a separate ventilating trap, as shown in detail on *fig. 1*, Plate IX[b]. Where, however, from the construction of the house and the arrangement of its drainage, such is not possible, as in some tenement houses, the above arrangement should *at least* be carried out.

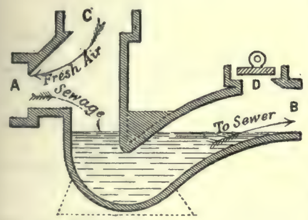

Fig. 284.—Buchan's Ventilating Trap, with Access Pipe.

The **Hart Trap** (Fig. 285) is a recent form of trap, advocated by sanitary engineers for disconnecting bath, rain-water, and such waste pipes from drains. It also is a ventilating trap. It is placed at the foot of the waste pipe, which discharges openly immediately below the level of the ventilating grating. The shape of the trapping portion is such as to secure a complete flushing of the trap, and a thorough washing out of all solid material into the drain.

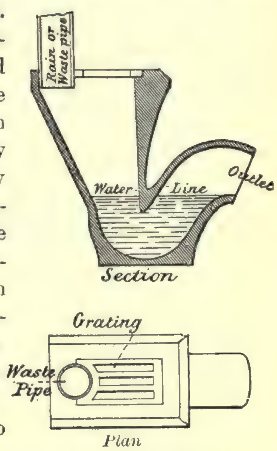

Fig. 285.—The Hart Trap.

The **Gully Trap** is a form of disconnecting trap, placed outside the house in a yard &c., into which rain or waste pipes open, either above or immediately below the ventilating grating. Its form and arrangement are represented in Fig. 286. It is used where one desires to prevent the entrance into the drain of material liable to silt up and block the drain, such material as may be washed down from roof

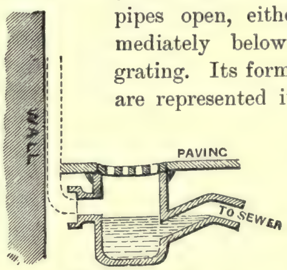

Fig. 286.—Gully Trap.

gutters, or washed in from yard sweepings &c., and which can be removed from time to time as it collects. In the case of the trap for a soil-pipe the shape is not the same, being such that the flushing water will wash everything down into the drain and prevent the interception of any solid material.

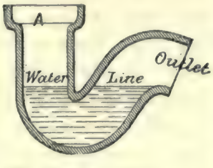

Fig. 287.—Syphon trap Surface Water.

A **Syphon-trap** for pipes, placed to receive surface water, is shown in Fig. 287. The top A is provided with a stoneware grating through which surface water passes.

Bad Forms of Traps.—The general form of trap of greatest use having been indicated, it may be well to give a warning against the use of some, whose employment is more likely to be attended by evil than good. Fig. 288 represents a form of trap which is a modification of the old form of cesspool. It is simply a cesspool, from the roof of which a slab of stone dips down

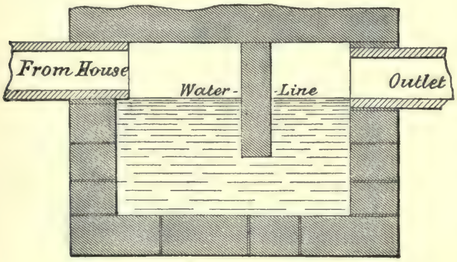

Fig. 288.—Dipstone-trap.

far enough to be below the level of the outlet-pipe, so that it enters the water of the cesspool. The effect of this is completely to divide the cesspool above the water into two chambers, not communicating with one another except through the water. Sewage gas passing up by the outlet-pipe would thus be unable to pass to the inlet-pipe. This is the **Dipstone-trap.** It is an exceedingly bad form, because excreta and decomposing material are certain to be retained in the bottom, because of the very shape of the cesspool, and foul gases will pass off directly on the side of the inlet-pipe.

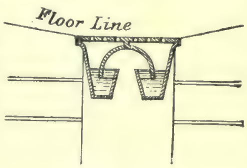

Fig. 289.—Bell-trap.

The **Bell-trap** (Fig. 289) shows a form of trap condemned by almost everyone, and yet very extensively used for carrying off the surface water from outhouses, dairies, washing-houses &c. It is quite commonly found in the basement of houses, where there are stone floors, and a pipe is laid to carry off water running upon them. It is called the **bell-trap**, because of the shape of the cover. It is a square box-shaped trap into which the drain opens, as shown. The box is covered by a grating, to the under surface of which is attached a cup or bell-shaped piece. Water is retained in the box till it rises to the level of the opening of the drain, when it passes down. The cup projects downwards lower than this level and thus dips into the water. While water can pass freely through the grating, over the bell and enter the drain, sewage gas is prevented by the layer of water between the opening of the drain-pipe and the rim of the bell from gaining the grating and passing into the house. When such a trap is in a washing-house floor, to carry off the water with which the floor is flushed, it is quite common for it to become blocked by the dirt &c. washed in, and then it is common, in order to let the water away, for servants and others to scrape away the cement from the edge of the grating and lift it a little. The bell is thus lifted out of the water and communication between the house and the drain is made perfectly open. Moreover it requires very little water to fill the trap; some of them hold little more than a teacupful. The consequence is that the evaporation of a small quantity of water will so diminish the amount in the trap that the entrance to the drain is completely exposed, and the seal is no longer effective. Such a trap would, therefore, be the worst possible, where frequent fresh supply of water does not occur, or where the heat is so great that rapid evaporation occurs, as in the floor of a furnace-room. So apt is this kind of trap to become inefficient that it is now universally condemned, and ought never to be used inside a dwelling, or dairy, or laundry.

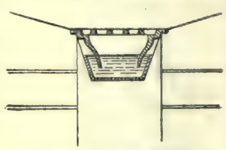

Fig. 290.—Liverpool Bell-trap.

The **Liverpool trap** is another form of the bell-trap, and open to the same objections. Fig. 290.

Ventilation of Traps and Drains is the second condition now invariably insisted on in any system of drainage designed to meet modern sanitary requirements. This ensures the continual removal of foul effluvia from the pipes &c. by a constant current of fresh air. For it is to be observed that efficient ventilation implies not only that there shall be a way of escape provided for foul gas, so that it can never

accumulate so as to force the trapping water, but also that an inlet for fresh air shall also be provided, so that there shall be an actual current to remove foul air and keep the atmosphere in the pipes constantly as pure as possible. How are these objects accomplished? Inside the house all traps should have a ventilating pipe, such as is shown in the case of nearly every house-trap in Plate IX[b]. The ventilating pipe either itself passes up to open on the roof, or opens into a pipe which is continued to the roof. All outside traps should be constructed on the principle illustrated in Fig. 284. It is evident from these figures that no accumulation of gas can occur in such traps. Fig. 291 illustrates how, with such arrangements, a constant fresh-air current is secured. It represents three water-closets, A, B, and C, on the three floors of a house, discharging into the same soil-pipe, S S. At the foot the soil-pipe is provided with a disconnecting trap T by which it is cut off from the sewer. But if the soil-pipe terminated at X, which it might naturally be supposed to do, there could be no current through the soil-pipe. When, however, the soil-pipe is continued upwards, full size, to open at the roof, then air entering through the trap grating G passes right up the pipe, clearing out all foul air and securing efficient ventilation. In the same way traps connected with wash-hand basins, baths, sinks, &c. should have a pipe connected with a main ventilating pipe open both at the foot and top to secure the same end.

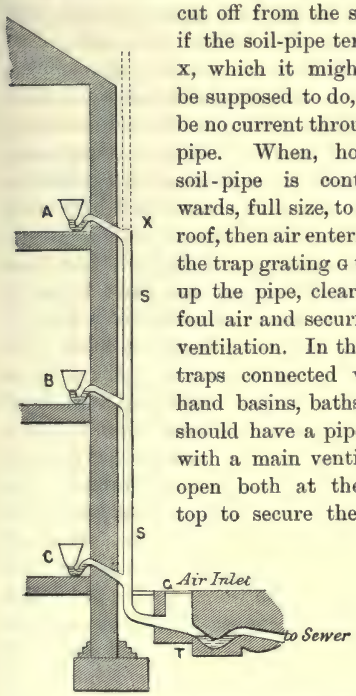

Fig. 291.—Faulty Method of Disconnecting and Ventilating Soil-pipe.

This is further illustrated in *fig. 1*, Plate IX[b].

Drain-pipes, Sewers &c.—Traps, however well devised and ventilated are only one means to the end desired, namely a house free from sewage emanation. One is too apt to think that in a multitude of traps is safety, and to ignore other equally important means of securing proper drainage. Strict attention must also be paid to the drain-pipes, the material of which they are made, the position in which they are laid, the manner in which one length of pipe is connected to another, and in which one drain joins another, and so on.

Material of Pipes.—Pipes inside the house (called **house-pipes** to distinguish from the pipes outside leading to the sewer, to which it is desirable to restrict the term **drain-pipes,** to avoid confusion) are usually made of lead or iron. Lead is very commonly used for greater ease of manipulation. The pipes should, in such a case, be made of drawn lead rather than soldered or seamed lead. Lead pipes for use inside should be $\frac{1}{8}$th inch thick, and should weigh 8 pounds per foot. Junctions should be made by means of wiped joints. Iron pipes are objected to by some because of their rough interior surface giving points of adhesion for particles of soil. When they are used they ought to be of the best quality and of smooth finish, and a porcelain-lined pipe is to be had, recommended for its cleanliness and durability. Iron pipes are somewhat readily corroded; but lead pipes are more easily eaten through by rats or cut by nails, &c. The former are usually 4 or $4\frac{1}{2}$ inches in diameter. They should be coated by Dr. Angus Smith's process, or by the Barff or Bower-Barff process, for the prevention of rust.[1] The thorough joining of such pipes is a matter of some difficulty, requiring careful and skilful plumbing work. The joints of iron pipes are often made inefficient by changes of temperature causing expansion and contraction of the metal and loosening the joint. The junctions should be well caulked and leaded; putty should never be used. Where such a pipe passes down inside a house against a wall, the part of the joint next the wall is difficult of access, and the work is often badly done, sewage gas being permitted to escape directly into the house through the faulty joint. Drain-pipes should be made of glazed earthenware, preferably salt-glazed. Porous earthenware pipes are, on no account, to be used, nor brick-built drains. They are easily broken, and permit leakage into the soil, and

[1] In Dr. Angus Smith's process, the pipes, heated to 700° Fahr., are immersed in a mixture of coal-tar pitch and linseed-oil heated to 300° Fahr., where they are left till they cool to 300° Fahr. Then they are removed and set to cool in a vertical position. In the Barff process, the iron is carefully cleaned, and is exposed, in a chamber kept at a very high temperature, to the action of superheated steam. The steam is decomposed by the heat, and a deposit of black oxide of iron—magnetic oxide—is produced on the pipes, which protects them from rust, the more effectually the greater the heat to which they were exposed, and the length of time they were exposed to the process.

then the hot atmosphere of the house will draw the foul air from the soil, the foundations of the house being also constantly damp.

Mode of Junction of Pipes.—The glazed earthenware drain-pipes should be socketed, so that the end of one section terminates inside the socket or flange of the other. The one pipe should properly fit the other, and the junction should be completed by cement, not mortar or clay. At proper intervals, drain-pipes should be provided with special inlets for inspection and cleaning purposes. Sections of pipe are made with such inspection eyes which pass upward to or near to the surface and are provided with a properly-fitting cover, sealed with mortar or putty. Round these access pipes a manhole may be built provided with a cover, which may be simply a flat stone, with a ring in it, bedded in cement or mortar. It is very necessary to see that drain-pipes are provided with a firm bed. If the soil is a made-up one, in particular, it will readily yield and the pipes may thus become broken or distorted. Where special care is being taken, it is advised to provide a cement bed, along the whole length of the drain to its junction with the sewer, care being taken that at appropriate intervals small cement chambers are built to admit of access for cleaning or inspection. Large-sized pipes should never join smaller ones; and when a junction is being effected between pipes of different sizes it ought to be by means of tapering pipes. The average diameter of drain-pipes is from 4 to 6 inches.

Junctions with drain-pipes should never be effected at right angles; the one pipe ought to pass gradually into the other, so that the current is not interrupted, the entering current having very nearly the same direction as that in the drain that is being entered. For similar reasons sharp turns are to be avoided, with their inevitable slowing of the current and tendency to encourage deposition of sewage matter. Pipes with curves to suit all kinds of turns are now provided, and their use should always be insisted on. Careless and indifferent workmen, to save themselves the trouble of securing such curved pipes, have been too often known to knock a hole in the side of one pipe, through which the end of the connecting pipe is passed, the space being filled up with cement, or not filled up at all.

Drain-pipes should always have a proper fall; the best practice is to allow a fall of 1 inch to each yard.

Position of Pipes.—It is customary for the pipe from the water-closet—the soil-pipe—to pass down inside the house, receiving branches on its way, from closets on different landings, or in the case of tenements, from closets from different houses, and being also joined by the waste from the bath, wash-hand basin &c. It often also receives the waste from kitchen, scullery &c., all the soil and waste from the dwelling indeed passing into the soil-pipe, which ultimately joins the drain at the basement. Now this is a bad system, for if any leakage occurs in any part of its course, if any faulty joint exists, and as already stated the changes of temperature, to which the pipe is subject, are very apt to make the joints leaky in time, the house gets the whole benefit. If there is any defect in fittings connected with the kitchen, scullery &c., the connection of their waste-pipe with the soil-pipe will ensure the entrance of gas into the house. It is, therefore, the first maxim of a sound sanitary system that the soil-pipe is carried out of the house as quickly as possible. It should pass down the back wall of the house. The branch from each closet should pass as directly as possible through the wall to join it, and in this way it can receive as many branches as may be deemed necessary. There ought to be no difficulty, in constructing a house, in placing the water-closet against the wall of the house so that there need be no long branch pipe to connect with the main. If any leak occurs in the course of the pipe, the sewage gas escapes into the open air, where it can do less damage, unless in the event of a window being in the immediate neighbourhood. The soil-pipe should be carried up to the roof, its full diameter, to act as a ventilating pipe. With such an arrangement, the closet basin having a trap beneath it, all fitting being properly made, and the soil-pipe passing outside through a disconnecting trap (Fig. 284), there should be no risk whatever from human excreta. If in addition to closet basins, the house is provided with a urinal, it also would be trapped inside and its discharge pipe would join the soil-pipe. If possible the soil-pipe should not pass near to windows, lest gas from a leaky joint should enter the house by the open window.

All other waste-pipes, pipes from bath, basin, sink, scullery, wash-house &c. should enter a separate pipe, having nowhere any connection with the soil-pipe. It also should pass down outside the house, receiving the various branches on the way, each branch having a separate trap upon it, just underneath the bath, or basin, or sink, as the case may be. This waste-pipe also should be disconnected from the drain by a dis-

connecting trap. If the soil-pipe is trapped at the foot, the waste pipe could terminate in the open air, discharging its water into the same trap through the grating, or the pipe might open into the trap, just beneath the grating, the soil-pipe opening at a lower level. If, however, the ventilating trap on the soil-pipe is at some distance from the house, as is desirable, the best arrangement would be to have a trap for the wastes alone, such as the Hart trap (Fig. 285), into which also rain-water pipes from the roof could discharge, all opening in the air over the grating or immediately under the grating.

Where it is at all possible to avoid it, drain-pipes should never pass under a house. If they leak, the house gets the full advantage either because of the direct escape of sewage gas, or because of effluvia from the soaked soil. The soil-pipe and waste-pipes should always connect with the drains, *outside of the house*, and if it is necessary for the drain to pass from back to front of the house, it should be carried round outside. Where it is unavoidable that the drain pass below the house, the utmost care should be exercised in its laying and jointing. It ought to be laid in cement, and at appropriate intervals access chambers, provided with air-tight covers should be provided, so that whenever necessary the drain could be inspected or cleaned, without unnecessary disturbance. It is not unusual to find a drain altogether outside of a house and yet practically opening into it at the basement, because of a rain-water pipe carried under the floor space to join the drain. As the pipe is only to carry rain-water, probably no great pains have been expended on its junctions, and perhaps it joins the main drain directly, without the intervention of a trap, with the notion of serving as a ventilating pipe for the drain. The result of the whole arrangement is that the warm air of the house sucks sewage gas, direct from the drain, through the defective joints of the pipe, as it passes beneath the basement, and the drain is literally being ventilated into the house.

Common Defects in House Drainage.

Defects in the Soil-pipe.—It has already been noted that it is a serious error to carry the soil-pipe through the interior of the house, if it is at all possible to carry it outside. It is often made to pass through rooms, pantries, larders &c., which ought not to be permitted. It is frequently not ventilated at all, or is ventilated only by a pipe of much smaller diameter than the soil-pipe itself. Sometimes the rain-water pipe is made to serve as a ventilating shaft for the soil-pipe, and it may terminate at the eaves in close proximity to a window, through which its foul air may be discharged into the house. If we summarize defects of workmanship in the kind of pipe used, in the making of joints &c., and the dangers arising because of want of disconnection between the soil-pipe and the main drain, defects already incidentally alluded to in noting the correct methods of arranging for the soil-pipe, there remains yet one frequent source of mischief. The cistern from which the flushing water for the closet is derived is also frequently the same cistern from which water for the domestic purposes of the household is obtained. The cistern is provided with an overflow-pipe, and this pipe is not uncommonly connected with the soil-pipe, so that the soil-pipe may actually be ventilated into the water, which is subsequently used for cooking and drinking purposes. The closet ought to be provided with a cistern for itself, and its overflow-pipe ought to be made to discharge into the open air.

Defects connected with Waste Pipes.—Waste pipes are very frequently made to enter the soil-pipe untrapped, or they join a rain-water pipe, which has a direct connection with the main drain. The rain-water pipe, in such a case, is supposed to act as a means of escape of foul air from the drain, but the arrangement almost ensures the entrance of gases from the drain into the house. Moreover rain-water pipes are quite usually carried down inside a house between the outer wall and the plaster, and if their joints are defective, as they almost always are, not only is foul air drawn into the house, but in the case of storm, when the pipes are running full or may be partially blocked, water also escapes between the walls.

Defects to be looked for in drains are numerous. Improper—porous—material is employed; joints are badly effected; sometimes one pipe is simply shoved into another, no cement being employed; if a piece of rock is being crossed in the bed of the drain, a lazy workman may chip off a piece of the pipe socket to avoid chiselling out a piece of the rock; a hole may have been driven into the pipe for inspection purposes, and subsequently covered only with a slate; the soil may have subsided causing cracking of the drain; or the house may have settled and the drain may have been crushed, for want of a protecting arch where it passed through the wall. In all these ways material may be permitted to soak into the soil, the emanations ultimately reaching the house.

The soil-pipe, drain, and main sewer may be in direct connection with one another, no trap intervening.

What has been said as to the means of preventing drains polluting a dwelling and the usual departures from sound methods is illustrated by the two following figures.

How a House Ought Not to be Drained is illustrated in Plate IX[a], which exhibits a plan of a self-contained house or villa. *Fig. 1* shows the ground-plan and *fig. 3* a section. The reference letters are the same in both. D D D D is the main drain which passes from front to back *underneath the house.* It is partly made of fire-clay pipes, and partly a brick-built drain. It terminates in a cesspool C built of brick, which is provided with a dipstone. The faults of this arrangement are: (1) The drain runs under the house and the house gets the full benefit of any and every leakage that occurs; (2) the earthenware pipes forming the front part of the drain are simply pushed into one another with no properly cemented joints; (3) the curve in front is not effected by curved pipes but by straight pipes, the flow from one pipe to the other will be impeded, and the drain is apt to be blocked; besides, the leakage will be very great; (4) the walls of the drain throughout are porous and leakage into the soil will occur all along, sewage emanations being drawn from the soil into the house owing to its warmth; (5) the cesspool acts simply as a retainer of foul putrefying material, leakage also occurring and being meant to occur from it; (6) the dipstone does not impede the backward passage of foul air, for foul gas is generated on the house side of it as well as on the sewer side, and the dipstone is so placed as to be perfectly useless (see *fig. 3*). The house pipes are thus in direct connection with the sewer; (7) the drain has no proper fall; (8) the drain passes through the foundation walls (at F, *fig. 3*) without any precaution to prevent damage through subsidence.

From the main drain branches pass off to various apartments. Beginning near the cesspool, **the first branch, 1**, is partly a brick-built pipe passing in under the washing-house floor, and ending under a grating (G, *fig. 1*) for the removal of surface water. The pipe from the tubs passes directly into this branch. The faults here are threefold: (1) This branch passes directly into the main drain and thus leads off sewer gas straight into the house; (2) the wash-tubs and surface grating communicate directly with the branch, untrapped, and (3) the mode of junction of the pipe from the tubs with the branch is one which tends to encourage deposit occurring in the branch. The **second branch** from the main drain is a rain-water pipe, 22′ 2″ (*fig. 3*), which passes up the end of the house and has a branch opening under the window W, for running off the rain-water from the roof, R, while it terminates at the eaves at 2″, near the upper part of the same window. The fault here is serious, for this pipe being in direct connection with the main drain acts as a blow-off for foul gas which it discharges beneath and in a line with the top of the window. Any time the window is open sewage gas will gain access to the house from it.

Branch 3 goes to the long hopper closet, a bad form of closet. (See p. 717.) It is faulty besides (1) in that the trap is not ventilated, and (2) the pipe from the w.c. enters the drain in a direction against the current (see *fig. 1*), and thus excreta will always be retained in the pipe.

Branch 4 (shown in *fig. 1*, though not seen in *fig. 3*, because of the position of the section) is the waste-pipe from a bed-room basin. Its faults are (1) its direct connection with the drain causes it to lead off sewage gas into the bed-room; (2) leaky joints make it a more certain conductor of foul air into the house; (3) it is ventilated by a pipe opening into the flue of the bed-room fireplace. In warm weather, when no fire is on, and when the atmosphere of the room is cooler than that of the outside air, there will be a down current of air into the room, and this will carry with it the foul air from the pipe.

Branch 5 leads to a scullery sink. (1) It also is in direct connection with the drain; (2) the only protection against the entrance of foul air from the drain is the leaden trap (*fig. 3*); but it has been pulled out of shape by the workman when the joint was made, and the water no longer stands high enough to act as a seal; (3) the scullery sink is so placed that the servants' back is always to the light; the sink is, therefore, dark.

Branch 6 is the soil-pipe. It is connected (*fig. 3*) with a pan-closet and receives also the waste from the bath (B), while it is continued to the roof to act as a ventilating pipe, and also as a rain-water pipe (6″) for the roof, while it receives the overflow pipe (6′) from the cistern, this pipe being connected merely by a slip-joint. The evils of this arrangement are enormous. (1) The soil-pipe is practically unventilated for no fresh air can enter the main drain to sweep up the pipe; (2) The w.c. is of the worst pattern, the pan w.c. (see p. 717); (3) the bath waste

PLAN AND SECTIONAL ELEVATION OF VILLA.

Fig. 4. The Pan Closet

Plate IX[a]

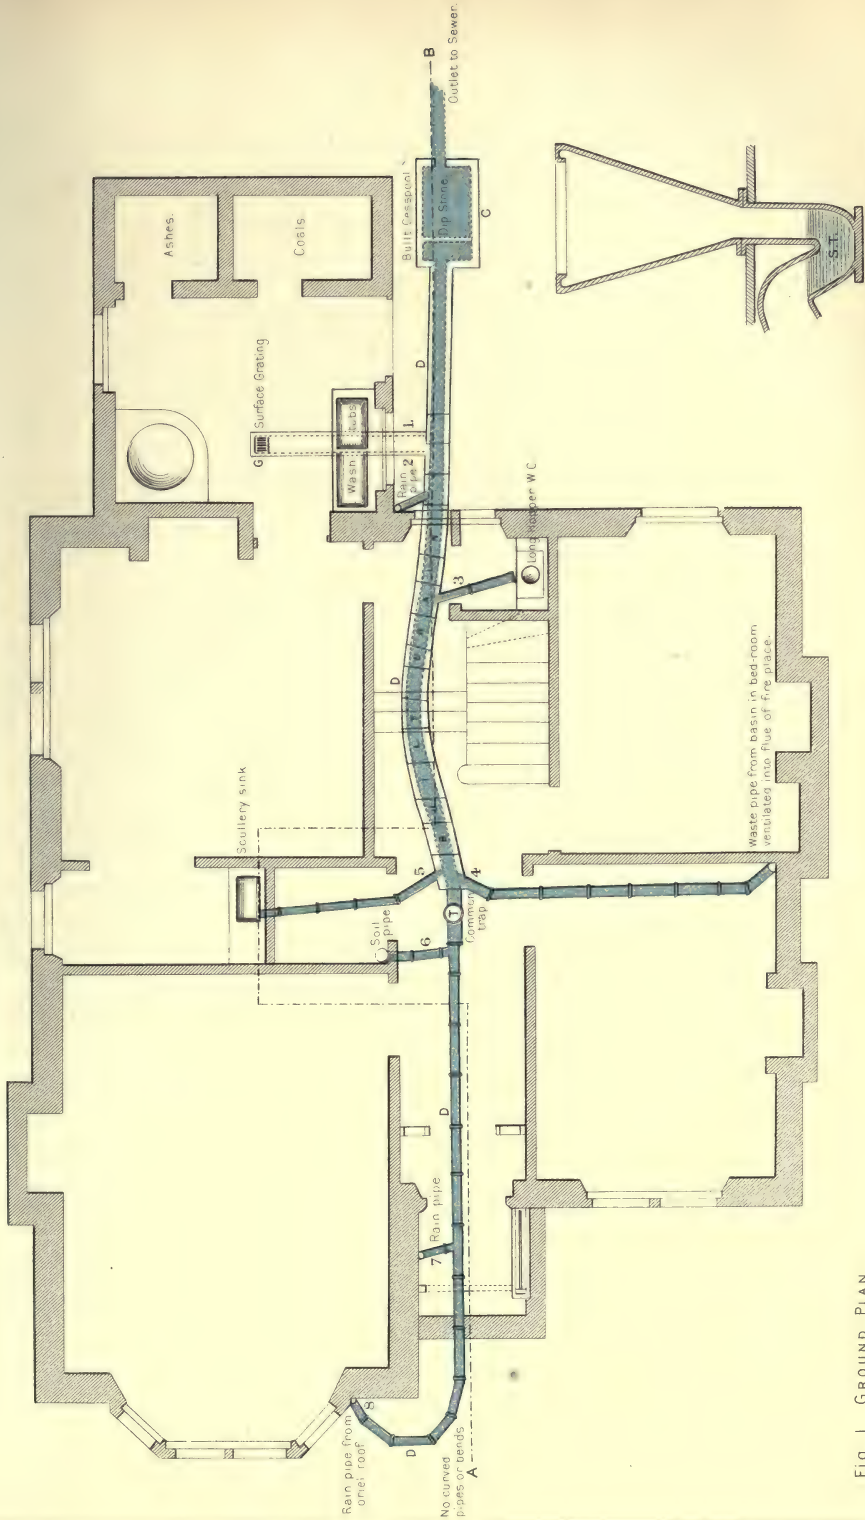

Fig. 1. Ground Plan.

Fig. 3. The Hopper Closet

enters the D trap of the w.c., which is certain always to be foul, and thus the waste-pipe simply leads off the foul air of the trap into the apartment; (4) it is a great mistake for the continuation of the soil-pipe to be made a rain-pipe, the risks of blocking being serious; (5) the water of the cistern is certain to be polluted by gas escaping up the overflow pipe, which also secures that the soil-pipe shall be ventilated, not into the open air but into the air of the house.

The trap T is an excellent illustration of the foolish way in which traps are sometimes employed. It is placed under the house floor, so that it is impossible to make it a ventilating trap. It simply acts as a detainer of the excreta coming down the soil-pipe, so that instead of that material being swept out of the house as quickly as possible it is detained for a longer or shorter period in the trap, and it prevents the possibility of any current of fresh air passing through the drain.

Branch 7 is for a rain-water pipe, but the pipe falls short of the entrance to the drain, and a constant soakage of the soil occurs from water missing the drain, while sewage gas pours into the soil from the open drain.

Branch 8 is a rain-water pipe, defective because (1) of its direct connection with the drain, and (2) because it terminates below a window in the gable.

How a House Ought to be Drained is illustrated in Plate IX^b. The upper figure shows the ground-plan, the lower a section. It represents the same villa as Plate IX^a. The chief features of the system there shown are these: I. The drains are all outside the house, and all house pipes are carried outside the walls as speedily as possible; II. there is no pipe for the removal of waste water in direct connection with any drain; III. the soil-pipe is kept entirely separate from the rain and waste pipes, the two systems being disconnected from one another by means of ventilating traps.

Let us study these figures to understand how these things are managed. We shall begin with the outfall to the main sewer O, which is a 6-inch glazed earthenware pipe, with joints caulked and cemented. The first thing to notice is the ventilating trap (V T^1), a 6-inch trap of the Buchan type (Fig. 284). This trap at once disconnects the whole of the house drainage from the common sewer. Entering that trap there are two drains, S D^1 and S D^2.

S D^1 is a glazed earthenware pipe drain, 6 inches in diameter, joints being caulked and cemented. Communicating with it are three different house-pipes, namely the soil-pipe from the upstairs w.c., the waste-pipe from the scullery sink, and the rain-water pipe, carrying off the rain-water from the roof and receiving also the waste water from the bath. These arrangements are shown in dotted lines in *fig. 3;* in dotted lines because a section such as is represented in the figure would not actually display them.

Taking the soil-pipe first, observe (1) that it passes right up to open above the roof, tapering out as it opens (S P, *fig. 3*); (2) that the w.c. is trapped (T) before it enters the soil-pipe, and that the trap has a pipe (V) passing off its highest outer point into the soil-pipe so that the air current through the soil-pipe prevents any accumulation of gas on the soil-pipe side of the trapping water; (3) that no waste or rain pipe enters the soil-pipe; (4) that the w.c. is of the Bramah type; and (5) that the w.c. has a special cistern (C^2) for flushing water, and has no connection with the cistern (C^1) supplying the house with water for domestic purposes. Observe lastly that the soil-pipe is continuous with a drain which has no direct connection with any other house-pipe, all waste or rain-water pipes in communication being cut off from direct connection by ventilating traps. It should be noted that apart from the trap connected with the w.c. there is no trap whatever on the soil-pipe or the drain it joins, till we reach the disconnecting trap V T^1. The result is that air entering the inlet grating of V T^1 (see *fig. 1*) passes right up the drain S D^1, and escapes at the top of the soil-pipe above the roof, so that there is a constant current of fresh air through the drain and soil-pipe. This is a preferable arrangement to having a ventilating trap on the soil-drain, at the point marked **X**, for example, near to some of the house windows, provided the length of drain before the ventilating trap V T^1 is reached be not too great. If, however, this distance were great, say more than 30 feet, a ventilating trap might be interposed sooner, provided it were out of the way of windows. Next let the scullery arrangements be noticed. The sink (S) is brought over to the window space (*fig. 1*). Its waste-pipe W P is trapped, and opens outside immediately under the grating of a grease-box (G B, *figs. 1 and 3*), the outflow from which joins the soil-drain.

Thirdly, the rain-pipe from the roof, R P, is disconnected from the drain by a Hart trap, H T (see Fig. 285). This rain-water pipe receives the waste from the bath B, the waste-pipe being

trapped (T) before it enters the rain-water pipe (see *fig. 3*).

Returning to the ventilating trap, $V T^1$, let us follow the drain, $S D^2$. It is a 4-inch glazed earthenware pipe. (1) It passes straight into the servants' w.c., which is a wash-out closet, and (2) it is continued, outside the house ($S P^2$, *fig. 3*), right up to open above the roof as did the other; (3) the pipe from the w.c. is trapped, and the trap has a ventilating pipe, T, leading into the soil-pipe. This closet is also supplied with a separate cistern.

This drain ($S D^2$) receives two main branches, one opening on the right, the other on the left (*fig. 1*). A very short way on, however, each of these branches is cut off from direct communication with the soil-pipe drain by a ventilating trap, $V T^2$ and $V T^3$. The right branch has two divisions, one (1) is a pipe removing waste water from the washing-house tubs and washing-house floor, and the other (2) carrying rain-water from the washing-house roof. The waste from the tubs is, however, trapped just under the tubs (see *fig. 3*), and the pipe running off the water from the floor communicates with the floor through a syphon trap (S T, *fig. 1*). Moreover, the trap of the tubs is supplied with a $1\frac{1}{2}$-inch ventilating pipe carried to the roof. The rain-water pipe has no trap apart from the ventilating trap $V T^2$, and thus a free current of air from the inlet grating of that trap is allowed right up the rain-water pipe.

The branch, R D, to the left (*fig. 1*) is cut off from the soil-pipe drain, $S D^2$, by the ventilating trap $V T^3$. It receives two rain-pipes from the roof $R P^1$, $R P^2$, which are not trapped at their base, and it also receives a waste-pipe, W P. This is the waste-pipe carrying off the waste from the bed-room basin, which in Plate IX^a is shown as branch 4 and was ventilated into the bed-room flue. It is in Plate IX^b continued to the roof as a rain-water pipe. In the bed-room the waste would be trapped under the basin, and from the trap a ventilating pipe would be carried to join the upward continuation of the pipe. For additional security this combined waste and rain pipe opens at its base into a Hart trap (H T) (*fig. 1*, Plate IX^b).

To this description of the two plates one need only further add that the soil-pipes, in the properly constructed drainage system, are all heavy cast-iron pipes, with caulked and leaded joints, that the inside traps are made of drawn lead, the pipes ventilating the traps are drawn lead pipes, $1\frac{1}{2}$ inch in diameter, any junctions being effected by means of wiped joints. The drains, as already noted, are all of glazed earthenware with joints properly cemented.

Plate IX^a shows also the space for coals and ashes opening into the washing-house, and thus in free communication with the air of the house. Plate IX^b shows this remedied by the communication with the house being built up, and direct openings to the outside being substituted.

Testing Drains.—There are several methods adopted for determining the soundness of a drainage system. One of these methods consists in pouring oil of peppermint, or other volatile strong-smelling substance, mixed with hot water, down the soil-pipe from its opening above the roof, and searching in and outside the house for any place where the smell of the oil indicates a fault. Sulphur may be burned on the house side of the disconnecting trap; and if any escape into the house, its presence will be detected by the smell, and the existence and position of the leakage will be thus indicated. The common method in use is the smoke test. Oily waste, sometimes sprinkled with sulphur, is burned in a covered box communicating with the drain, or if the system is trapped, with the house side of the trap. By means of a fan turned by a handle, or a small bellows fitted to the apparatus, air is driven into the box and the smoke driven into the pipes. If any leak exists the smoke will readily gain access to the house and be detected by the smell. When the pipes are filled with the smoke so that it issues from the openings above the roof, these are usually blocked, and the air continues to be forced into the pipes. Smoke is in the pipes at pressure and a leak is readily detected. The doors and windows of the house should be kept closed, to confine any escaping fumes to the apartment into which they enter, so that the locality of the leak may be more readily found. Another method consists in blocking the drain at some point outside of the house or at the outflow end of the trap, and running water into the pipes from sinks, baths, closets &c. till the pipes are full. The pipes should remain full, but if they leak the level of the water will fall, and the amount of leakage may be estimated by the water it is needful to keep running to maintain the level. The appearance of wetness in walls &c. will indicate where the leakage is occurring.

Flushing of Drains.—To keep drain-pipes as clean and free as possible from deposit, frequent flushing with water is needful. The larger the body of water with which this is done the better. A constant dribble of water is not nearly so effective as an occasional rush of a large quantity.

In all houses there is a continual flow of waste water from wash-hand basins, baths, rain-water pipes &c. which is not very effective for cleansing purposes, as it ordinarily is allowed to escape, but which if collected and allowed periodically to escape in a body into the pipes would flush them very thoroughly. Such water might be collected in a tank in connection with the drains and might be supplied with a self-acting arrangement, which, when the tank was full, would cause the water to be discharged into the pipes till the tank was empty, when the communication would be closed till the tank was again full. A considerable number of tanks have been patented for this purpose, of which Field's is one of the best known. It

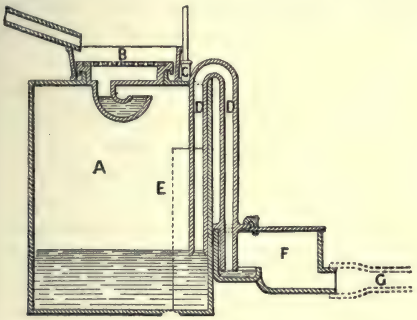

Fig. 292.—Field's Flushing Tank.

A, Tank. B, Trapped inlet. C, Ventilating pipe. D D, Syphon. E, Strainer for grease &c. F, Discharging trough. G, Outlet to drain.

is illustrated in Fig. 292. It is a tank fixed underground, the feed of which may be supplied with rain-water, or bath waste, or by means of a tap direct from the main. Towards one end is fitted a syphon arrangement, DD, one limb of which is long and opens below into water of the trap, F. This limb rises to the height of the top of the tank and then bends over, passing down into the tank to open not far from the bottom. As the inflowing water rises in the tank, it also rises in the inner limb of the syphon till, when the tank is full, it reaches the bend at the top, over which it passes. The syphon action is thus automatically started and the water continues to flow out by the syphon till the water in the tank is brought down to the level of the opening of the inner tube. The tank is in short rapidly almost emptied, and the body of escaping water effectually flushes the drain. As soon as the water in the tank falls below the level of the opening of the inner tube, air enters, and the syphon action stops. The tank again begins to fill and the water continues to rise, till the syphon is again set in action by the water reaching the level of the bend of the syphon. Beyond the trap the outflow pipe enters the drain, G, and the trap prevents the backward passage of sewage gas into the tank.

It is now necessary to make a few references to some of the interior arrangements for the disposal of waste.

The Water-closet first of all demands our attention. The old form of water-closet, now universally condemned but still to be found in houses, is shown in Plate IX^a, *fig. 4*. It is placed here as a useful example of defects to be avoided. It is called the **Pan Closet**. The basin, B, is the part visible, the other portions being concealed beneath the seat. At the outlet of the basin is the pan, P, lowered by raising the handle, by which means also the inflow of water is occasioned from the cistern above, which washes out the soil. The basin opens into the container C, and that opens, by the pipe shown, into the D trap, which again leads into the soil-pipe. Now the inside of the container, as is evident from the figure, will be continually coated with excrement splashed up upon it, which no amount of flushing can remove. The D trap is also certain to be constantly foul from the same cause. Thus the trap and container are always full of foul air, delivered into the house every time the handle is pulled up. It is the shape of the closet which makes it bad. It does not matter of what material it is made, it is not possible to keep it clean.

The chief thing to be desired then in a water-closet is a form which, by its very shape, guarantees the effectual scouring off from every part of it of every particle of adherent excrement. The pipe leading from the tray or safe for carrying away any water that may overflow is usually made to open into the trapping water, and thus it ventilates the trap into the house. It has been found opening directly into the soil-pipe, and thus leading off foul gases from the soil-pipe into the house. It ought however to be taken through the wall to the outside, being provided with a flap-valve to prevent entrance of cold air.

The **Hopper Closet** shown in Plate IX^a, *fig. 2*, is another form condemned for a similar reason: it does not admit of the flushing water cleansing every portion of its interior, and a great deal of material is likely to be retained in the syphon-trap shown below S T.

Wash-out Closets.—There are now in the market many forms of water-closets which avoid the defects which have been noted. They are commonly made of some kind of earthen-

ware, the basin and the trap beneath being all in one piece. *Fig. 2* of Plate IX^b, shows one of these kinds where T is the trap, S leads into the soil-pipe, and V is a ventilating-pipe. By means of this pipe if the soil-pipe communicates with a disconnecting trap, and the soil-pipe is open to the roof there is a guarantee of a constant current of fresh air preventing any accumulation of foul air in the trap.

The **Valve Closet** or **Bramah Closet** shown in Plate IX^b, *fig. 4*, is one which meets with commendation. The figure also illustrates how it ought to be connected with the trap T. The safe placed on the floor to receive any water which escapes over the basin, should be provided with a waste-pipe, passing directly outwards and opening in the outer air. The external opening ought to be provided with a flapper to prevent the inrush of cold air.

Flushing Water.—A good form of closet being secured and properly set up, the next thing is to see that a full supply of flushing water is provided. This depends upon the size of the service-pipe. The supply ought to be sufficient to fill the overflow-pipe O (*fig. 4*, Plate IX^b) every time the handle is drawn.

The Connection of Water-closet and Cistern demands attention. The cistern is certainly provided with an overflow-pipe, and the important question is where does that overflow-pipe go to. It is probable that it enters the soil-pipe, or the water-closet trap, or passes directly to the drain itself. In such an event the waste-pipe is simply tapping the foul air of the drain, trap, or soil pipe, and conducting it into the house. It may connect with the waste-pipe of the bath, wash-hand basin or scullery sink; and to all of these connections there is the same objection. In cases where the house is not supplied with water for domestic purposes direct from the main, but where the same cistern supplies the water to be used for cooking and drinking purposes, the evil is a double one, for the water is being contaminated by the sewer gas, and the household is not only breathing a polluted atmosphere but is drinking polluted water. The waste-pipe ought in all cases to pass to the outside and open in the open air. No cistern supplying water for domestic purposes should be connected with any water-closet, or other arrangement for the removal of excreta. Where the water supply is provided from a cistern, the closet ought to be supplied by a separate cistern, which, if it must be supplied from the main cistern, may be by a disconnecting method which shall guard against any contamination of the drinking water.

Fig. 293.—Arrangement of Waste-pipe from Scullery Sinks.

Sinks.—The sink requiring special attention to be paid to it is the scullery or kitchen sink, for into it there passes a large quantity of greasy material, which readily adheres to the inside of the pipes, to the sides of the traps, and to the walls of the drain, and which in large establishments will clog up the drains sooner or later. For such large establishments a grease-trap is necessary, a trap fixed outside the house, into which the pipe from the sink enters, and of which the outlet-pipe to the drain is so arranged that the grease is retained and collected for periodic removal. Concerning grease-traps Eassie says they are required, "never in cottages, seldom in small houses, sometimes in the larger dwellings and villas, where cook and scullery-maid reign below stairs, and always in houses where the number of servants outnumbers the family. This is a very skeleton definition, but it is all my space will allow. Where a grease-collection trap is necessary, unless that accommodation be rendered, the underground drains will choke up, and necessitate their being opened up and cleaned out. The need for a grease chamber is enhanced when the culinary utensils are scoured out with sand at the scullery sink, and if a chamber be not provided, the drain will clog all the sooner, as the sand does not get to the sewer, but becomes embedded in the grease." Where a grease-collection trap is not necessary, it is needful only to recal what has been already said on p. 713, that the sink waste-pipe should not open into the soil-pipe but have a separate house-pipe,

that that pipe should open in the open air either over or immediately under the grating of a disconnecting trap, preferably of the gully form, by which any sand and other solid waste may be intercepted, lest its entrance into the drains obstruct them. Such an arrangement is shown in Fig. 293.

Bath and wash-hand basin wastes are similarly treated, and all are trapped within the house by the syphon trap (s) shown in Fig. 293. The form of syphon for sinks connected with kitchen, scullery, wash-house, &c. ought to be the access-syphon, illustrated in Fig. 294. The screw in the bottom of the trap permits of opening the trap for the removal of any retained solids which cannot be washed away readily.

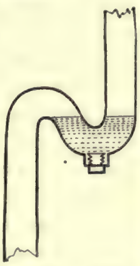

Fig. 294.—Access-syphon.

Grease Traps are shown in Figs. 295 and 296. Owing to the depth of the lip of the trap, the layer of floating grease is prevented passing into the drain, and can be removed at intervals.

It has been questioned whether, provided the sink waste is provided with a system separate from the soil-pipe, and is properly disconnected from the drains, as shown in Fig. 293, any trap immediately under the sink is advisable, and whether it is not rather objectionable from its risk of retaining decomposing materials, grease, soap-suds, and the like. If the waste-pipe were to pass directly through the wall and were very short, no such trap might be needed, but it is needed where the sink is any distance from the place where the waste-pipe opens, and where the waste-pipe is consequently of some length. For the grease, soap &c. retained in the pipes, occasion very objectionable smells, which would be drawn into the house by its warmth. Where the pipes are of some length, indeed, not only is the trap desirable, but it is also advised that a ventilating pipe be led off from the outer side of the trap and be carried to the roof, so that a draught of fresh air is passed through the pipe to keep the air sweet.

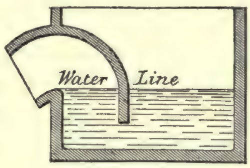

Fig. 295.—Grease-box.

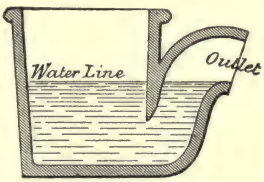

Fig. 296.—Grease-box.

Drainage and Water-supply.—Where the water is supplied from mains there is little risk of pollution from drainage. Care ought, however, to be taken that the service-pipes are not in proximity to the drains, and hot-water pipes ought not to pass through the house alongside of cold service-pipes, causing the heating of the cold water. Attention ought to be given to the position of the cistern provided in connection with boilers for heating water for domestic purposes. Such cisterns are usually placed in out-of-the-way corners, covered in and never examined as to their cleanness. It is too common, according to Eassie, to find it placed in the darkest corner of the commonest stowaway cupboard, with its overflow pipe connected with the drain. "On one occasion," he says, "in a large town house in the west of London, the servants complained that the hot water drawn from the tap at the kitchen jamb tasted badly, and was of the colour of weak tea, which was no wonder, for an exploration of the feed cistern in the cupboard led to the removal of several basins full of drowned black beetles, in all stages of dismemberment."

Whenever the water-supply is obtained from wells, great precaution must be taken that the water is not contaminated by sewage before it reaches the house. Collections of dust, refuse, and rubbish of various kinds in the neighbourhood of the well are certain to lead to its pollution. For the water from the heap percolates into the soil and in due time reaches the water. Cesspools near the well are specially to be guarded against. Leaky joints in the drains, which permit the escape of sewage, are also a frequent cause of contamination. If any of the drain-pipes, instead of being of glazed earthenware, are made of porous material, leakage into the soil occurs, and the water-supply of the well will get a full share.

Cisterns.—The water-supply of the house, when derived from a well or a stream, may be pumped up into a cistern in the house, or led thither by gravitation if the source be higher than the house. In such an event the cistern exposes the water to pollution, supposing it may have escaped previous contamination. Cisterns of sawn slate are to be preferred. Those of stone or brickwork cemented inside are also cleanly and useful. Galvanized-iron cisterns are unobjectionable. Wooden cisterns lined with lead are common. The risk of contamination of the water with lead has been spoken of on p. 642. An insoluble salt of lead is soon formed which coats the metal and pre-

vents any such poisoning of the water. This should never be scraped off. When the cistern is cleaned, and every kind should be periodically cleaned, at least once a year, a scrub with a hard brush is all that is necessary. Cisterns of wood only should never be employed, because of their certainty to decay and because they afford material for the growth of low forms of vegetable life. Zinc-lined cisterns are also objectionable. When the cistern is lined with lead, if the water has been retained in it for any time unused, through the house being shut up for example, the standing water should be run off and a fresh supply allowed to enter. Indeed in every case this should be done.

Cisterns should never be inside the roof space of a house, but whenever possible in the open air. They ought to be covered but also ventilated. The trouble of cisterns outside is their liability to frost. This may be greatly diminished by a proper lining of wood, or by a surrounding space filled with saw-dust, or by a lining of inodorous felt. The overflow-pipe should open directly into the open air.

Dry Methods of Removing Excreta.

It is often not possible to remove excreta from dwellings and towns by water carriage, either because the water is not at hand, or because there is not sufficient fall for a due outflow or for other reasons. Even where water carriage is possible the pollution of streams and rivers, which it usually involves, makes it desirable to find other means. Various other methods of removal have therefore been suggested and adopted. The refuse solid and liquid may be received in tanks and boxes and these may be daily removed and their contents applied as manure to land. The land must be at some distance from dwellings, however, and in the case of large towns the expense of collection and cartage becomes great.

The Dry System of removal consists in mixing the excrement with dry earth, ashes, or other material, which absorbs moisture, delays putrefaction, and prevents smell. The mixture is then applied as manure to land. It is necessary in this system that slop water, waste water from sinks &c. be excluded and removed in some other way. For schools, country houses, villages and small towns, it is a convenient and desirable method, under certain conditions. These are that sufficient of the mixing material be provided, in a perfectly dry state, to cover up the excrement and absorb the watery portions, that the mixture is frequently and regularly removed, that the closet is in a position as separate from the dwelling as possible, and that it as well as the place for the pan, pail or other receptacle is properly ventilated.

Moule's System is the proposal of the Rev. Henry Moule, by which dry earth is mixed with the excreta. The absorbing power of dry earth is very great, and the mixture is quite inoffensive. The apparatus required for this system consists of a pail to receive the excreta, and of a hopper which holds the dry earth. The arrangement is such that when the handle of the closet is pulled a proper quantity of earth is thrown into the pail.

Charcoal or various deodorizing substances may be substituted for the dry earth. The earth after removal may be prepared for use again by allowing the organic matter to become destroyed by putrefaction and driving off the moisture by heat. Fine dry cinders may also be employed.

In **Morrell's Arrangement** cinders are thrown upon an opening leading to a sieve placed in connection with a closet. The fine ashes pass through the sieve and are retained till by a movement of the seat of the closet a quantity is thrown upon the soil, the larger ashes pass over the sieve to a pail placed below.

The **Goux System** provides a tub "say 16½ inches high and 20 inches at its greatest diameter. Upon the bottom of the tub are placed 3 or 4 inches of refuse, such as new stable-litter, loft sweepings, stack bottoms, ferns, shavings, saw-dust, shoddy, flax-dressings, spent tan, or hops, or the various waste materials to be found in the town or country. This is mixed with a little soot, charcoal, gypsum, or other deodorizer, for the purpose of lining or packing the tub. A mould of the same shape as the tub, but six inches less than the internal diameter, is placed upon the four inches of absorbent material referred to, and the space between the mould and the tub is packed with the same kind of refuse. One boy can pack eighty tubs in an hour, and this is all the manipulation required, except in placing and removing the tubs at stated times. The absorbent material having been only moderately pressed down, the mould is withdrawn and there remains a cavity into which the dejections fall, the liquid parts of which are taken up by the absorbents, and retained by them so as to check fermentation."

Such dry methods are only applicable on a limited scale, the preparation, storage, and transport of dry earth or other material, and

the removal of the excreta, involving in large towns enormous labour and expense, while it does not do away with the need of some water-carrying system for the removal of slop and waste water.

Sanitary Maxims.

In concluding our considerations of house-drainage, we may put the most important points to be attended to in brief space, in the following maxims selected from Mr. Pridgin Teale:—

1. It is the duty of every householder to ascertain for himself whether his own house be free or not from well-known dangers to health.

2. As a rule the soundness of the sanitary arrangements of a house is taken for granted and never questioned until drain-begotten illness has broken out. In other words we employ illness and death as our drain-detectives.

3. Whenever gas from sewers or the emanations from a leaking drain, a cesspool, or a fouled well, make their way into a house, the inmates are in imminent danger of an outbreak of typhoid fever, diphtheria, or other febrile ailments, classed together under the term zymotic, not to speak of minor illness and depressed vitality, the connection of which with sewer gas is now fully established. Sewer gas enters a house most rapidly at night, when outer doors and windows are shut, and is then perhaps most potent, in contaminating the meat, the milk, and the drinking water, and in poisoning the inmates.

4. The more perfect the public sewers of a town the greater the danger to every house, connected with such sewers, if the internal drain-pipes of the house be unsound, and not disconnected. In houses so misconnected *sewer air is laid on* as certainly for the detriment of health as coal-gas for illumination.

5. A house in which children and servants are often ailing with sore throat, headache or diarrhœa is probably wrong in its drainage.

6. Scamped drain work is one of the most dangerous of the sanitary flaws of new buildings; it is also one of the most common, and one of the most difficult to detect, and is rarely found out except by the illness it produces.

7. If you are about to buy or to rent a house, be it new or be it old, take care, before you complete your bargain, to ascertain the soundness of the sanitary arrangements with no less care and anxiety than you would exercise in testing the soundness of a horse before you purchase it.

8. If you are building a house, or can achieve it in an old one, let no drain be under any part of your house; disconnect all waste-pipes and overflow-pipes from the drains, and place the soil-pipe of the w.c. outside the house and ventilate it.

9. If there is a smell of drains in your house, or a damp place in a wall near which a waste-pipe or a soil-pipe runs, or a damp place in the cellar or kitchen floor, near a drain or a tank, let no time be lost in laying bare the pipes, or drains, until the cause can be detected.

10. If a rat appears through the floor of your kitchen or cellar, and a strong current of air blows from the rat-hole, when chimneys are acting and the windows and doors of the house are shut, feel sure that something is wrong with a drain.

11. If you are tenants and your landlord refuses to remedy the evil, do it at your own cost rather than allow your family to be ill.

12. Many a man who would be aghast at the idea of putting small quantities of arsenic into every sack of flour, and so by degrees killing himself and family, does not hesitate to allow sewer gas to poison the inmates of his house, even in the face of the strongest remonstrances of his medical adviser.

13. A landlord may reasonably look for interest on the money which he spends for the benefit of his tenant; but he is committing little short of manslaughter if, by refusing to rectify sanitary defects in his property, he saves his own pocket at the expense of the health and lives of his tenants.

14. If you be a landlord, don't intimidate your tenants, or threaten to give them notice to quit, if they complain of defective drainage, or sewer gas in the house.

To these we may add a final one:

15. Never use for domestic purposes water derived from a well situated in a street of town or village, or in proximity to dwellings. Be suspicious of water derived from any well in the immediate neighbourhood of a house or farm steading. However excellent it may appear, the risk of its being contaminated is very great.

SECTION V.—CLOTHING AND BATHING.

Clothing.

The Purpose of Clothing:
The Means by which the Temperature of the Body is normally maintained—Regulation of Temperature by the Skin.

The Qualities of Suitable Clothing:
Clothing as a Conductor of Heat;
The Absorption of Moisture by Clothing;
The Porosity of Clothing;
Practical conclusions regarding Material for Clothing;
Inflammability of Clothing;
Form and Shape of Clothing.

Underclothing.
Night Garments.
Dress for Women and Children.

Sea and River Bathing—Salt Baths;
Medicated Baths—Alkaline, Sulphur, Pine, Mustard, and Mud Baths;
The Douche, Sitz and Needle Baths.

The Uses of Baths in Disease.

CLOTHING.

The Purpose of Clothing is to aid in maintaining the temperature of the body at the proper, or normal level, that of 98°·4 Fahrenheit. It is not only that clothing is used as a protection against external cold, but it is employed also as a protection against external heat. It is evident that clothing must possess different qualities, according to the kind used, to enable it to fulfil these opposite conditions. Furthermore, we have said the purpose of clothing is *to aid* in maintaining the temperature of the body. Many people are too apt to consider that the heat of the body is maintained by clothing alone, and so they multiply wraps and coverings, regardless altogether of the material employed, and desirous only of interposing a thick enough layer between the surface of the skin and the cold atmosphere. When we say *to aid*, what is implied is that the body itself has the power of maintaining a normal degree of heat, which in some circumstances would be quite sufficient without any covering, but that when the variations of the external temperature are greater than the body can conveniently adapt itself to, some covering becomes a necessity. If clothing is then really to *aid*, regard must be had to the natural means by which the body endeavours to protect itself, so that the natural processes of the body may not be disregarded, abolished or subverted. By what means does the body maintain for itself a normal temperature? is naturally the first question. Heat is produced within the body, and heat is lost from the body. When the heat produced is equalled by the heat lost, the warmth of the body remains at the same level—there is a balance of heat production and heat loss. By the action of the nervous system, which it is unnecessary to consider in detail, the production of heat within the body may be increased or the loss of heat may be diminished to meet increased external cold, or the reverse may occur

to meet increased external heat. The chief means of heat production in the body is chemical combination, the combination of carbon and hydrogen of the food with oxygen, contained partly in the food and also introduced by the air of respiration (p. 532). If none of the heat so produced were given off from the body, it has been calculated that in 24 hours the temperature of the body would be raised to the boiling point. Of the energy produced by this chemical combination $\frac{4}{5}$ths or thereby are given off from the body actually as heat, while $\frac{1}{5}$th is converted into mechanical work. The loss of heat from the body takes place from the skin, from the lungs, in heating the cold air taken in by respiration, and some is removed from the body by the excreta from the kidneys and bowels. Fully three-fourths (77·5 per cent) of the total heat lost from the body are given off by the skin, nearly 20 per cent (19·9 per cent) is given off with the expired air, and a small percentage (2·6 per cent) is lost with the excreta. It is with the skin chiefly that we have to calculate in considering how the body parts with its heat.

The skin loses heat in four ways (1) by radiation, (2) by convection, (3) by conduction, and (4) by evaporation. The meaning of radiation, conduction, and convection has been incidentally explained on p. 699. Radiation doubtless is affected by the clothing worn, rough clothing radiating more rapidly than smooth. A single illustration will suffice to indicate how heat is lost by radiation. Suppose we sit with our back towards a damp cold wall, but not touching the wall, radiation takes place from the body to the wall, and may take place so rapidly that we speedily experience a sensation of chilling, which is commonly attributed to draught, so that it is quite usual to hear some one say, "there is a very cold draught along that wall," while it is simply that the body is rapidly parting with its heat to the wall by radiation. We have all practical experience also of the meaning of convection and conduction. We know that when we sit in still air, its coldness or its heat is not so perceptible to us, as when the air is in movement. Air is a bad conductor of heat, and, while the air is still, the body parts with its heat slowly, for the heat is but slowly conducted through the motionless air; but if a current of cool air play upon a part of the body we are speedily aware of its influence. The particles of air come in contact with the body, become warm and pass off, to be succeeded by other particles, each getting its share of heat so that the body is being quickly robbed of its heat by the myriads of air particles carrying off each one its share. It is, however, by evaporation of sweat that the skin parts with heat most rapidly, and by a variation of the amount of evaporation that the loss is regulated to suit circumstances (see p. 309). Now these facts must be kept in view if one is to appreciate fully the best means by which clothing will fulfil the purpose it is expected to serve, since clothing can be considered to be suitable only so long as it properly reinforces the natural bodily means of regulating the temperature. This will be most easily understood by illustrating how clothing ought to be made to aid the maintenance of an equable bodily temperature (1) in winter or in a cold atmosphere, and (2) in summer or in a warm atmosphere. We may say that in winter there is an increased heat production because of an increased quantity of food consumed, and food of a more heat-giving character, and that in summer there is a lessened heat production because of less food consumed or food of a less energy-yielding kind. Setting this aside, however, we may consider only the variations in the loss of heat.

In **Winter**, or whenever it is exposed to a cold atmosphere, the body adjusts itself to the altered external temperature by a diminished flow of blood to the skin and, in consequence, a diminished loss by evaporation. It is merely a diminution of the loss, not an arrest of loss. Evaporation still goes on but to a diminished extent. Suitable clothing, then, will aid this process by interposing a barrier to the conducting away of heat from the body, or, to look at it from the other point of view, interposing a barrier to the conducting inwards to the body of the external cold, and this it must do *while not interfering with a healthy amount of evaporation from the surface of the body.* For suppose clothing is put on of a kind or in such quantity as to prevent the insensible perspiration (p. 309) duly passing off, what happens? The vapour becomes condensed and remains upon the surface of the body as moisture. The body becomes enveloped by a fine film of water. Now water is a better conductor of heat than air, and thus the condensed vapour is a direct aid to more rapid cooling of the body than is natural, exactly the reverse of what one desires under these circumstances. This is the explanation of the ready chilling of the body after copious perspiration. The sweat has formed more quickly than it can be removed as vapour; it condenses and forms a watery layer which

facilitates the conduction of heat from the body. Many people heap clothes upon themselves and their children in cold weather, not only when going out of doors but also when indoors, and wonder why, in spite of all their wraps and precautions, they and their children feel and are so much subject to the cold. It is just because of their precautions that the tendency to cold manifests itself. Instead of aiding and abetting the healthy action of the skin, they interfere with and subvert it, creating the conditions for a too free perspiration, which, condensing as moisture on the skin, leads to a too rapid parting of heat from the body.

In **Summer**, or in a hot atmosphere, the warmth of the body would maintain its equilibrium mainly by a free but regular evaporation from the surface. Clothing should not interfere with this, and, therefore, ought to be of material which permits free passage to the vapour from the skin. But the clothing ought also to render service by being a non-conductor, so that the external heat may not be communicated to the body. It might be thought that in hot weather, the body should be clothed with material that is a good conductor of heat to enable the body to part more quickly with its heat. But if the external air be warmer than the body, the clothing that is a good conductor will rather conduct heat to the body than away from it. Even supposing the external air be slightly less than the temperature of the body and that, therefore, the clothing would conduct in the proper direction, conduction is not the method by which the body naturally parts with its heat to any great extent, and it is a method which does not act so uniformly, and regularly as that by evaporation. When conduction operates to any great extent, that is when the conduction is effected more rapidly than by air, it is apt to cool the body unequally by acting more on one part than on another; and chilling results. Moreover, clothing material that is good conducting material is as a rule less permeable to moisture, and would prevent the due evaporation of sweat, which would then condense upon the skin. Thus the loss of heat from the body would be accelerated in one way, and retarded in another, and in the chief way; while the risks of too rapid cooling of parts of the body would be incurred. In summer then the action of the skin would be aided by non-conducting material, which allowed free passage to the exhaled vapours, not only by the nature of the substance of which it was made, but also by the thinness and openness of texture of the cloth.

The Qualities of Suitable Clothing we are now prepared to understand more fully. (1) It should be made of material which is a bad conductor of heat. (2) The material should readily absorb moisture, so that the vapour of perspiration may be allowed to pass off from the body, and may not be caused to accumulate between the clothing and the skin, leading to condensation. (3) It should be more or less porous in texture, by which is meant that the cloth should be able to contain air in its meshes or fine channels. This will effect two objects. Air is a bad conductor, and a cloth which is so woven that it may contain a considerable quantity of air will be a better non-conductor than one of the same thickness so closely woven as to retain little air. The more porous material will, secondly, allow of movement of air in its meshes, of ventilation that is to say, and will be better adapted to permit due exhalation from the skin. These qualities of clothing we shall now consider in some detail, in order to learn what kinds of material possess them to greatest extent.

Clothing as a Conductor of Heat.—The following list shows the relative position which the different materials, used for clothing, occupy, the best conductors being placed at the head.

Flax and linen,
Cotton and calico,
Silk,
Wool,
Eider-down,
Fur.

The fur of the hare, according to Rumford, conducts least of all substances used for clothing, and next to it come down and wool. According to the same authority, if the conducting power of linen be represented by 100 that of wool is from 50 to 70. Putting this in a popular way, of two coverings of linen and of wool both of the same thickness and texture, the woollen one would be nearly twice as warm as the linen one. Though it is put in this way it must be remembered that there is no actual warmth in either, the meaning is simply that the linen conducts the heat away with nearly twice the rapidity of the wool; that the wool, in other words, retains the heat and thus maintains the warmth of the body. In the same way the woollen material would retard the excess of heat from the outside. Thus ice wrapped up in wool will melt more slowly than if exposed to the warm external air, for the wool keeps out the heat. Between linen and cotton cloth—calico—there is no great difference. Thus, in an

experiment, the same degree of heat was imparted to linen and calico, and it was found that the former cooled down in 10½ minutes and the latter in 11½. Linen is, however, actually the best conductor of all materials used for clothing, and, therefore, the least desirable of material for that purpose. This conduction of heat is not affected by colour; it is determined by the material of which the clothing is made. Moreover it is to be distinguished from the absorption and emission of heat, which colour affects to a considerable extent. What is meant by the absorption and emission of heat will be understood by comparing heat to light. A substance which permits light to pass is called transparent, it does not absorb the light; a substance which absorbs the light—does not permit it to pass—is called opaque. Now we may say some substances are transparent to heat, that is, they allow the heat to pass through without absorbing it, so that in consequence they do not become warm. This is true of air, the heat rays from the sun or from a fire pass through it without warming it. Other substances do not permit the heat to pass through, they are opaque to it, so to speak, they absorb it. Substances which absorb heat also give out the heat or emit it, later. Thus glass is transparent to light, but it is not so to heat. It absorbs the heat rays. If one is sitting in front of a fire and, feeling the heat too great, interposes a screen of glass, at once the intense heat is diminished, but the light is unaffected, the fire is plainly seen through the glass screen. The screen has been cold before it was placed in front of the fire, but it soon grows warm; that is to say, it intercepts or absorbs the heat rays, and therefore becomes warm, and by and by emits the heat. It is useful under such circumstances, for it prevents the heat being poured in a too intense stream on one place; but the heat is not lost. It is given out later in a more gradual and pleasant fashion, warming the room more regularly and comfortably. This illustrates what is meant by absorption and emission of heat, and how it differs from conduction, for glass is not a good conductor. In the same way clothing may absorb heat and emit heat apart altogether from conducting power. While colour does not influence the conduction of heat to any extent, it seems to have a marked influence on the absorption of heat. This is of importance as regards the gain of heat to the body from without. Thus suppose two garments of the same material, thickness &c., but one black and the other white, and suppose the sun's rays to be playing equally upon both, the black garment will absorb much more heat than the white one because of its colour alone, and the individual wearing the black one will feel the heat much more intensely than the individual wearing the white garment. Thus experiments were made to determine the amount of heat that would be absorbed in the same time by material made of different substances, cotton, linen, flannel, and silk, but all white, and comparatively little difference was found between them. When, however, shirtings *all made of the same material*, were used, but *all of different colours*, the amount of heat absorbed was found to vary very markedly with the colour.

Thus when white shirting	absorbed	heat to	raise it to	100° F.
pale-straw shirting	,,	,,	,,	102° ,,
dark-yellow ,,	,,	,,	,,	140° ,,
light-green ,,	,,	,,	,,	155° ,,
dark-green ,,	,,	,,	,,	168° ,,
turkey-red ,,	,,	,,	,,	165° ,,
light-blue ,,	,,	,,	,,	198° ,,
black ,,	,,	,,	,,	208° ,,

Scientific facts are, therefore, in agreement with the facts of experience in testifying that light-coloured garments are coolest for summer wear, and dark-coloured warmest for winter wear, not because they conduct the heat differently, but because the light garment absorbs least of the sun's rays and black absorbs most. So in summer we use the garment which, because of its colour, will refuse to absorb much heat, and in winter we adopt the colour which will absorb most and aid in keeping up our bodily warmth.

The Absorption of Moisture by Clothing.—The power of absorbing moisture is a most important quality of clothing. It is according to the degree to which clothing absorbs moisture that it does not interfere with the natural exhalation from the skin. If the material covering the body readily takes up vapour, then the perspiration passes into the clothing and is given off on the outside; but if the absorptive power of the clothing is little, the body is kept enveloped in an atmosphere saturated with vapour, and with the slightest exertion becomes bedewed with moisture—a most uncomfortable

position to be in, and one which is attended by considerable risk of catching cold, as we all know. This quality of absorbing moisture is called the **hygroscopic property** of clothing material. This property has received careful investigation at the hands of Pettenkofer, who took pieces of different materials, all of the same size and weight, and having carefully dried them at 212°, weighed them, and thereafter exposed them to the atmosphere of different places, more or less damp, for varying periods. He then weighed them to discover how much moisture had been absorbed. The following are some of his results:—

After 12 hours in a cellar	there had been absorbed	by linen	77	parts of water,	by flannel	157	parts.
,, ,, ,, room	,, ,,	,,	41	,,	,,	75	,,
,, ,, ,, laboratory	,, ,,	,,	69	,,	,,	105	,,
,, 10 minutes ,, room	,, ,,	,,	73	,,	,,	113	,,

Results of other observations are shown in the following table. Various materials were taken of the same weight, dried in a hot chamber for 24 hours, and then exposed (1) for 48 hours in a cold uninhabited room, and then weighed. The same materials after drying were exposed (2) for 72 hours in a damp cellar, and thereafter weighed. The results were as follows:—

	Weight at the End of the 1st Experiment.	Weight at the End of the 2nd Experiment.
Sheep's wool,	1084	1163
Fur,	1072	1125
Eider-down,	1067	1112
Silk,	1057	1107
Linen,	1046	1102
Cotton,	1043	1089

The weight of each substance before exposure was 1000.

With flannel, according to Pettenkofer the maximum power of absorbing water is represented by 174 and the minimum 111, while with linen the maximum was 75 and the minimum 41. He took two pieces of flannel and linen of equal weight, put them into water, and then wrung them out till no more water could be squeezed out. He found that for every 1000 parts of weight of the flannel 913 parts of water were retained, and for every 1000 parts of linen only 740 of water were retained. He also proceeded to determine the rate at which wool and linen gave off water with which they had been wetted, and observed that wool dried more regularly than linen, the water being given off rapidly from the linen at first and then more slowly, but from wool with less rapidity to begin with but more steadily, so that in the end more water was given off from the wool than from the linen in the same time.

Now what is the bearing of these facts? It will be observed that the order of absorptive power for moisture is just the order of non-conducting power for heat, so that the clothing material which conducts heat least is the material which absorbs moisture most. Such clothing, when covering the body, will conduct the heat from the body with least rapidity but will interfere least with the natural evaporation of sweat. These, as we have seen, are exactly the conditions one desires in suitable clothing. It is the kind of covering for the body which will interfere least with the natural means by which the body regulates its temperature. Suppose the body to be engaged in active exercise, by which a large amount of perspiration is induced: if linen be next the skin, it will speedily become saturated with moisture, and the uncomfortable feeling of soaking garments will soon arise. If woollen clothing be worn, the wool will absorb much more moisture before it becomes saturated, and the active exercise will be engaged in for a considerably longer period before the discomfort is experienced. Then suppose the person sits down to rest, rapid evaporation will immediately take place from the linen, and the heat of the body will be quickly reduced, a feeling of chilliness being the result, while the evaporation from the woollen material will be more gradual, so that a natural process of cooling will result with much less chance of chilliness. "In other words, a person after violent exertion may sit down on a cool bank, if dressed in a flannel shirt, with less danger than if his dress were linen."

There is another point of view from which this quality of clothing must be considered. Suppose the moisture does not come from the body but is external, suppose, that is, that one is in a damp atmosphere, then the woollen clothing will absorb the moisture from without more rapidly than the linen; and this may seem to be to the disadvantage of the former. But then the woollen clothing will be able to take up more water before it is saturated than the linen, which will become speedily soaked, so that the disadvantage is, in this way, counterbalanced. One will, therefore, be able to bear exposure to the damp atmosphere longer without discomfort when clothed with woollen material.

Clothing can be made impermeable to moisture by various means, and the body may thus be protected from external damp by an outer covering of impermeable substance. This will appear all the more desirable when we consider the greatly increased weight woollen garments must have when soaked with moisture. If 1000 parts of flannel can take up 157 parts of water, a woollen garment which, when dry, weighs 10 pounds may take up enough moisture to weigh 11½ pounds. The added weight which the body will thus require to carry, if one wears a long heavy woollen garment, such as an "ulster," is not too insignificant to be taken into account. Impermeability to moisture is conferred on cloth by various methods. Mackintosh's patent, by which what is called Mackintosh is produced, applies a varnish made of a solution of caoutchouc in rectified petroleum or naphtha between two layers of cloth. A similar varnish may be laid on one side only of the cloth. A solution of caoutchouc in linseed-oil is also employed, and linseed-oil boiled with sugar of lead. A solution of soap may be also used worked into the cloth and then acted on by a solution of alum. This prevents the passage of water into the pores of the cloth; or if the cloth be impregnated with a solution of isinglass or glue, and then acted on by a clear infusion of galls, a similar effect is produced. For rougher material hot tar is employed. Of all these methods those of Mackintosh are the most used, the solution being applied either between two layers of cloth or on the outside of the cloth. The cloth prepared by the first method is most sought, because of its appearance, but that prepared by the second is in some respects the better, because, being quite on the outside, it prevents any moisture being taken up from without, while, in the former case, the outer layer of cloth becomes soaked and consequently heavier.

Such impermeable material, however, illustrates the disadvantages of wearing clothing not capable of absorbing moisture, if it be worn for any time. The natural evaporation from the body is interfered with, and a feeling of oppression is produced, while perspiration collects on the skin. Such material should, therefore, be worn for as brief a period as is really necessary, and should be removed as soon as the necessity is passed.

The Porosity of Clothing depends to some extent upon the material of which it is made, but chiefly on the manner in which the cloth has been woven, its closeness of texture being the chief circumstance modifying it. By porosity is meant the extent to which air may penetrate the cloth, because of spaces, channels, pores &c. The porosity of various materials has been determined by finding the amount of air that could be forced through a piece of the cloth with a certain pressure in a given time.

Through	flannel	10·41	measures of air passed.
,,	lambskin	6·07	,, ,, ,,

Pettenkofer obtained results showing that in the same time in which flannel allowed 100 measures of air to pass

Linen and buckskin	allowed	only	58
Chamois	,,	,,	51
Silk	,,	,,	40
Kid	,,	,,	1

In short the clothing that experience admits to be the warmest is that which conducts heat least, absorbs water most easily and allows the air the freest passage. That clothing which permits air to pass most readily should be the warmest may seem at first sight to be strange and unexpected. When we consider, however, that the meshes and canals of porous clothing are filled with air, and that air is a non-conductor of heat, the explanation is forthcoming. To speak of a covering of air might seem an absurdity, but in plain fact when one wears a porous garment one is kept warm, not by the cloth covering alone, but also by the layers of air which occupy the interstices of the cloth. Now the porous garment will readily admit of the removal of the products of perspiration, and will not interfere with the function of the skin.

The porosity of clothing has a marked relationship to the non-conducting power of cloth. The conducting power of a material does not depend upon porosity but upon the nature of the material itself. Nevertheless the looseness or closeness of the texture of the cloth will modify the conducting power, just because with a loose cloth the non-conducting power of air is brought also into play. Thus Krieger employed tin cylinders which he filled with hot water, and he noted the rate at which the cylinders cooled when they were enveloped with different substances. In one observation he covered the cylinders with loose common wadding, and found the tin parted with its heat slowly: then he compressed the wadding, and the temperature fell much more rapidly. In short by compressing the wool he diminished the air spaces in the wool,

and expelled much of the air, and thus lost the benefit of the air covering. For similar reasons a tightly-fitting covering permits of a more rapid loss of heat than a loosely-fitting one. The tightly-fitting one, by its close application to the body it covers, permits the full action of any conducting power the garment may possess; while the loosely-fitting one has its conducting power for heat largely set aside because a layer of air is interposed between the garment and the body. In the sense already explained a person who wears loosely-fitting clothing may be said to wear next the skin a garment of air, and retains much warmth of body on that account. This explains also how it comes about that two thin garments are warmer than one garment equal in thickness to the two put together. The two garments have between them a layer of air and thus actually present a greater thickness of non-conducting material, because of the film of air, than the single thick garment. For this reason it is better, instead of having light flannels for summer wear and heavy flannels for winter wear, to use the same thinness of flannel summer and winter, but to put on more in winter than in summer, to wear two in winter and one in summer.

Practical Conclusions regarding Material for Clothing.—The facts that have been considered show that under all circumstances woollen material is the most suitable for clothing. It conducts heat least, it absorbs most moisture, and it permits most readily the passage of air. It is well fitted to aid the skin in maintaining a normal temperature, without interfering with the proper functions of the skin as an organ of excretion (see p. 308). For summer or for winter it is alike valuable, modifications in the quantity of clothing worn, in the number of garments, in the closeness or openness of the texture, being alone necessary to meet the very different conditions of summer's heat and winter's frost. While valuable in every climate, in none is it more valuable than in that of the British Islands, where dampness and rawness of atmosphere are prevailing characteristics, because, by its ability to absorb a large amount of moisture before being saturated, and afterwards to permit the moisture to evaporate gradually, it prevents sudden and great diminution of the bodily temperature, which would certainly be the result of cotton or linen clothing. For precisely the same reasons is it pre-eminently valuable in hot climates, where the intense heat of the day gives place, immediately on sundown, to a rapid cooling; when persons are at one time broiling in the sun and soon afterwards shivering with cold. It is these sudden changes of temperature that clothing should be specially fitted to modify, and no article of clothing material is so suitable for such a purpose as wool. Again it is the best protection to the person who, for one reason or another, has little active exercise to assist in the production of heat within the body; and it is the only really safe article of clothing for any engaged in very active or even violent exercise followed by periods of inaction, as in the games of cricket, football, tennis &c. At the period of violent exercise the person wearing woollen garments will certainly feel warmer than another clothed in cotton or linen, but the woollen material permits the normal activity of the skin in its effort to maintain the balance, while the cotton or linen upsets it by greatly increasing the conduction of the heat from the body. The result is seen as soon as a pause in the exertion occurs, when the person clothed in cotton becomes aware that his clothing is soaked with perspiration and fears he will begin to feel chilly immediately, while the other individual is quietly, naturally and comfortably cooling down. Woollen clothing should then always be worn next the skin. The garment should be of only moderate thickness, not too close in texture, and should not be tight fitting. Whenever it becomes necessary to increase the amount of clothing it should be preferably by the addition of another garment to the first, not by substituting a thicker one for the first.

In cold weather the garment should be black or of a dark colour, in hot countries or at hot seasons it should be white or light-gray.

Knitted woollen underclothing is the best, but it should be neither too fine nor too close. It used to be objected to woollen underclothing that it was too heavy for summer weather. But woollen garments can be obtained of any required thickness, and a woollen garment of the same weight as a linen one is much warmer. An objection in which there is more of truth is that woollen material next the skin is irritating. It undoubtedly stimulates the skin, and if rough reddens it markedly. Flannel especially has such a disadvantage. But of recent years so much attention has been given to the manufacture of the wool for such purposes and to the knitting of undergarments, that the objection has now much less force. Woollen underclothing can be obtained as soft and fine and non-irritating almost as any linen garment could be. There are, however, a few people, not many,

who find wool next the skin really irritating, no matter in what form it is. They should not, therefore, abandon woollen underclothing, but may protect the skin by interposing between it and the wool a fine large-meshed gauze garment. In such cases silk might be worn next the skin.

One objection, however, to woollen underclothing of some force is that it shows dirt much less quickly than other materials, and that, in consequence, it is often worn unchanged for far too long a period. This, however, is scarcely a disadvantage pertaining to the material itself, but properly is an evil to be laid to the door of the wearer.

Inflammability of Clothing.—It is worthy of notice that woollen material, which we have found so thoroughly to answer all the requirements of healthy clothing, is also one of the substances least open to objection on the ground of risk of catching fire. It will burn slowly, will smoulder, but will not easily burst into flame. Cotton and linen, on the other hand, will readily burst into flame and be rapidly consumed. A linen or cotton dress, pinafore, or apron, taking fire will speedily flare up, the flame spreading from one part to another, till the whole is in a blaze, and the flame is not easily altogether extinguished. When such a garment catches fire, serious and fatal injury may be occasioned before it is put out. If a woollen garment is similarly exposed, the fire does not quickly extend, is more limited to the one place, and may thus be arrested before harm is done. The more dense the fabric the more slowly does the combustion proceed. Leather has a similar advantage. Silk is more inflammable than wool, but much less so than either cotton or linen. Whenever the occupation exposes the person to risks of fire, woollen material should invariably be selected. Of all articles of dress, muslin, from its openness of texture, is most dangerous. The plan of extinguishing fire on clothing by enveloping the person in a blanket, rug, shawl &c. is based upon the small inflammability of the wool of which the blanket &c. is formed.

It is possible, however, to render linen, muslin and other cotton goods non-inflammable by impregnating them with some material, which resists fire. Of such substances the most useful is tungstate of soda, and molybdate of soda. The former is that chiefly used. These substances are dissolved out in washing, however, and the material requires re-treatment with the solution after each washing. The tungstate of soda permits the material to be ironed without change being produced; it does not injure the material either in texture or appearance, nor does it affect the colour. Other substances, used for the same purpose, either do not stand ironing, or change the colour of the garment, or give the material an unfinished appearance. Sulphate of ammonia, for example, which is cheap, a ten-per-cent solution of which renders a garment, dipped into it and then dried, non-inflammable, affects some colours, especially madder-purple. Phosphate of ammonia, also used, gives a "chalky" finish. Material made of asbestos absolutely resists fire. It may be heated to redness without being consumed. The other materials chemically treated, while they do not burst into flame, will yet become charred. "Fire-proof starch," recommended for muslins, &c. is starch prepared with tungstate of soda; and when used as ordinary starch it renders the material non-inflammable.

The Shape and Form of Clothing should have regard to these conditions: (1) The clothing should not be tight-fitting, for reasons explained in the paragraphs relating to porosity of clothing; (2) It should not be redundant, necessitating the stowing away of unnecessary material; (3) It should nowhere exert undue constriction on any part. Increased tightness anywhere inevitably interferes to a greater or less extent with the normal circulation of the blood, leading to deficiency of supply of blood to the parts beyond the line of constriction and consequent coldness, or more certainly to slowing of the blood current returning by veins to the heart. A good illustration of this is the aggravation of varicose veins by constriction, as by the use of tight garters.

Underclothing should always and everywhere be of wool, for reasons already sufficiently explained in the preceding paragraphs. If it prove, as it sometimes, but not often, does, too irritating to the skin, a fine open-meshed garment of silk or lawn may be interposed between the woollen garment and the skin.

Night Garments should be of wool for the young, for the old and feeble, and for delicate persons, those liable to cold, lung affections, and for the rheumatic. In very cold climates they may be necessary for all, and they should certainly be worn by any, who are frequently required to get out of bed during the night. For persons in full health and vigour, however, under ordinary circumstances, a cotton or linen night-dress is to be preferred. It is far cleanlier to begin with. In bed, moreover, circum-

stances do not demand warm clothing. There is no exercise to induce perspiration. There are no sudden changes of temperature to be guarded against. There is no conduction away of heat to be feared. The bed-clothes should offer sufficient protection against that; and under such circumstances cleanliness is the main consideration. Moreover the stimulating effects of the wool in direct contact with the skin are not desired in bed, as they would tend to produce too great a feeling of warmth, and the skin to some extent should be allowed to share in the rest permitted to the other parts of the body.

"A man might as well sleep in his boots as seek repose in a night-cap," says Mr. Treeves, the London surgeon; and "for the majority of individuals the night-cap is no more an essential to health than it is a contribution to personal beauty." If that is true as regards men it is still more true when applied to women, whose copious hair affords all necessary protection.

Dress for Women and Children has already been sufficiently considered in pages 472, 444, and 452. It is only necessary to say that the reasons given for woollen underclothing apply to them with full force, in some respects with even greater force than to men, for women have, as a rule, less active lives than men, and children are much less able to stand any exposure to cold.

Dress for Men should fulfil the conditions already stated at length. Trousers should be suspended by braces from the shoulder, not by belts or straps, which exert undue pressure on the abdominal organs, and thus may increase any tendency to rupture. Still more are such appliances hurtful, or likely to be so, when used to enable increased exertion to be put forth, as in running, leaping &c.

Covering for the Head.—The hair is the natural covering for the head. It is a bad conductor of heat, it allows free evaporation of moisture, it is porous, and it is light. Thus it exhibits all the conditions of suitable clothing, and in its natural state is thus well fitted to afford protection to the head. In its natural state, we say, but it is seldom permitted to be in its natural state, for, when well oiled and well brushed down, it is both a better conductor and less porous than it ought to be. If oil or pomade be necessary for keeping a tidy arrangement of the hair, only so much should be used as is really necessary for that purpose. That the hair is in ordinary circumstances quite an efficient protection is proved by the large number of persons, even in the uncertain climate of Britain, who habitually use no additional covering. Some covering is, however, used by most people in civilized countries, partly for tidiness sake, and partly as an extra protection against cold, wet, or heat, as well as because custom demands it. Such additional protection should fulfil the same conditions applicable to coverings for any other part of the body. It ought not to conduct heat, it ought to allow evaporation of the perspiration from the scalp, it should not be heavy, nor should it constrict any part of the head. The ordinary tall hat worn by men violates all these conditions. It very commonly catches at front and behind; it is very likely to be heavy; and for want of ventilation it becomes a hot-air box confining the vapours from the scalp. Its faults are most conspicuous in summer, particularly when it is black in colour. It is, thus, prone to produce a feeling of weight and oppression and perhaps headache. Felt is an appropriate material for hats; and there ought to be no difficulty in making them properly fitting and light, but ventilation is not so easily effected, since that implies an opening for the entrance of fresh air as well as an outlet for the escape of exhaled vapour. Woollen or flannel caps need no such provision since they are made of porous material, provided that material is not of too close texture. Straw hats fulfil all the required conditions.

For protection against heat, the heat of the sun in summer, for example, the head covering should be of white material, and should be so shaped as to shield the back of the head as well as the top and the face. The ordinary broad-brimmed straw hat is the most useful for such a purpose. In excessively hot climates the back of the neck should also be protected by it. It should be so made as to permit the free passage of air through it. For India the pith or bamboo-wicker helmets, covered with cotton, are said to be the most suitable head covering, being of great advantage in diminishing the risk of sunstroke. In excessively cold climates, again, fur caps are the most suitable.

Covering for the Feet.—It ought not to be necessary to consider what is the appropriate covering for various parts of the body in detail, since the same conditions, already laid down on p. 729 and the preceding pages apply equally strongly to all parts of the body. We need only refer to one or two points in the clothing of the feet which transgress these conditions. If the general surface of the body should be clothed in non-conducting material, much more ought the feet which come into more or less direct contact with the ground, and can, therefore, be

more readily robbed of heat than other parts of the body. Cotton socks or stockings ought, therefore, never to be worn, but always woollen, the thickness being dependent upon the season. It should also be noted that if socks or stockings are knitted of too hard wool and too closely, they are less porous, contain less air in their meshes, will be more easily soaked and matted with moisture, and will afford less protection against loss of heat in cold and wet weather. Stockings or socks with a compartment for each toe, as gloves have for each finger, are warmer, more cleanly, and more likely to be better fitting than the ordinary kind. Then tight-fitting stockings are less warm and comfortable than the more loosely fitting, provided the latter do not exhibit the fault of the other extreme of too much material, requiring to be crumpled up in the boot. What has been said should also show how great an evil garters are. If they are to be useful at all they must be tight, and if tight they compress the veins, preventing the due return of blood from the foot and leg. The sluggish circulation thus induced is a frequent cause of cold feet, and of pain and weariness in the limbs of which women so commonly complain. It is besides a serious cause of enlarged (varicose) veins. Stockings should, therefore, always be kept up by "suspenders."

Boots are commonly far too stiff and unyielding to permit the movement of the foot proper to walking, unless in the case of women's boots when they often are far too thin to yield protection against cold or wet or even the mechanical discomfort of a gravelled walk. The spring of the step is taken from the ball of the toes, and here the boot should yield easily, so that a person ought to be able to stand on tiptoes almost as readily with boots as without them, the boot bending as the foot does. Unyielding boots not only interfere with this movement, but indeed with the free play of the whole foot, so that all the mechanical advantage and elasticity, derived from the foot being formed of numerous bones, jointed so as to form an arch across the foot as well as from heel to toes, is lost; and the foot moves in its inclosing box as a solid mass and not as a yielding elastic structure. The result of the constant wearing of such boots is that the foot actually loses its natural elasticity; the muscles of the foot not being allowed free exercise do not attain to full development and are permanently weak, and walking is a labour instead of a pleasure. Obviously the natural movement of the foot will not be permitted in boots which are made without regard to the shape of the foot. The outline of the foot should, therefore, determine the shape of the boot. In this respect many boots err in the narrowing towards the toes, which crushes the toes together, causing one to ride over the other. The heel, which ought to be nearly as large as the ball of the heel itself, is usually too small, too high, and placed too far forward. The high heel throws the body into the position approaching that of the person, walking on his toes, and disturbs the natural balance of the body, so that to maintain the erect posture more muscular effort is required, while its forward position practically destroys the value of the arch of the foot from before backwards. The weight of the body being thus thrown forward crushes the toes forwards against the points of the boots, and tends to bend the toes, and to press unduly upon the nails, deforming them and occasioning ingrowing toe-nails. The small heel affords far too narrow a basis of support, so that the body is unstable. For a man the heel should not be more than $\frac{3}{4}$ths inch high and should be placed well back. Boots, if properly fitting and of pliable material, do not press unequally upon any part, and thus avoid the causes of the production of corns and bunions, the result of undue and unequal pressure. At the same time boots ought not to be so large as to permit the feet to move about loosely within them. The friction so produced would quickly raise blisters and cause thickenings of the skin.

How often are all the evils that have been indicated exemplified to the full in the boots of children! They are bought large to suit their growth, and heavy that they may the less easily be knocked to pieces, and they are made to pass up the leg to give additional support to the ankles!!! So the child's feet are tied up in a box, and her toes are twisted and squeezed into a shape nature would never have produced, and muscle is wasted for the sake of economy in shoe leather, and the surest of all methods is adopted to produce weak ankles instead of avoiding them. The moderate and natural use of a part is the best means of strengthening it. It is with regular, but not excessive, exercise that muscles grow strong and well-formed. When such exercise is prevented by artificial bands and strappings, the surest means of inducing weakness are being adopted. Special care ought, therefore, to be taken with the covering for children's feet, since the growth will be powerfully affected by the nature of that covering. Probably shoes would be more

suited than boots, since they allow a freer action of the ankle joint, and they also allow, better than boots, of the escape of moisture from the feet. If, from the beginning, the child's feet are allowed free play in well-fitting shoes, pliable, and not so heavy as to tire out the young muscles with lifting them, there need be little fear of badly-shaped feet or weak ankles. But if under the name of strengthening weak joints, the natural growth and exercise of the muscles and ligaments of the foot and ankle are interfered with, weakness will certainly result, and the necessity of external support will become more pronounced as the child grows. The weakness, in short, which the mother points to as the proof of the need of the external support, is the result of the support.

Poisonous Dyes in Clothing.—There are on record numerous instances in which symptoms of poisoning have been traced to the clothing worn, dependent upon the stuff used to dye the material. The poison to be feared is arsenic, some of the preparations of which may be deliberately used for colouring purposes, such as the arsenite of copper, which is green; while some forms of arsenic are found as impurities in other colours employed. Thus magenta (rosanaline or fuchsine) which when pure is harmless, is sometimes contaminated with arsenic, and most of the cases of poisoning from clothing have been owing to this dye in the cloth. In the pigments known as cochineal red and coralline it has also been found. The effects so produced may be twofold. Arsenical vapour or dust may be given off from the fabric and be inhaled, leading to symptoms of chronic poisoning, perhaps for a long time not recognized as such. The usual symptoms are headache, sickness, loss of appetite, languor, feverishness &c. In the second place the clothing may directly irritate the skin, leading to redness, swelling and inflammation of the skin, producing perhaps an eruption. In all kinds of printed and woven materials, used for clothing, has arsenic been found, in flannel vests and shirts, in socks and stockings, in hats and gloves, in artificial leaves and flowers, as well as in table-cloths, carpets, wall-papers &c. It may be well to observe also that clothing is capable of absorbing not only moisture but also odours and emanations of various kinds. The extent to which such absorption occurs depends to some extent upon the colour of the cloth, black absorbing most, then the other colours in the following order—

Blue – Red – Green – Yellow – White;

the last absorbing least. That the contagion of infectious disease clings tenaciously to clothing and may be easily transported from place to place by it is well known, and is a means of spreading such diseases not too carefully guarded against. The relation between the absorption of odours and colour would seem to indicate that nurses in attendance upon any infectious disease should be clad in light-coloured washing dresses and not in dark garments.

BATHING.

The Uses of Bathing.—The primary use of the bath is for the promotion of cleanliness. Both from within and from without do materials accumulate upon the skin which, if allowed to remain, interfere with the proper and healthy discharge of its business in the bodily economy. On p. 387 and following pages the nature of that business has been pointed out. By means of the sweat-glands, and the sebaceous glands connected with the hairs, material is constantly being removed from the blood for expulsion from the body. But these glands may become easily blocked at their outlet, the excretion escaping with difficulty. From the surface of the skin dried scales of the scarf-skin are being separated in the form of fine dust. These, mingling with the moisture from the sweat-glands and the oily material from the hair-glands, form a material, readily remaining upon the skin, covering over the minute openings of the glands, and so interfering with the function of the skin, diminishing its activity as a purifier of the blood, and possibly leading to disease. Then from without dust &c. settles upon the skin increasing its defilement. The primary use of bathing is to cleanse the skin from such impurities. For these purposes the regular use of cold or tepid water with soap is effective, but it is not completely so. It removes the surface material but has less effect on the deeper parts of the glands, which are more effectually cleansed by the common practice of the weekly warm bath. By the latter means what may be called a flushing of the tubes of the glands is produced. The warmth brings a large supply of blood to the skin, and stimulates the glands to increased activity. The increased quantity of sweat thus produced causes, so to speak, a flow down the tubes and washes out any material which may have collected in their interior, which the daily wash may not have been sufficient to remove. This is even more thoroughly effected by the hot-air bath, one of the features of the Turkish bath. This is, indeed, one of the most valuable effects of the hot-air bath, the very copious

perspiration produced by the action of the hot air on the skin causing a very thorough clearing out of the gland-tubes or "pores of the skin," as they are commonly called. So that so far as cleansing purposes are concerned, the daily ablutions with soap and water, the weekly warm bath, and an occasional hot-air bath would be a most excellent arrangement.

All water for ordinary bathing purposes ought to be soft. The softer it is, the greater is its cleansing property, because the more readily does it soften and dissolve impurities. Besides, hard waters are liable to irritate the skin, and many persons are very liable to such irritation; and hard waters are very uneconomical in soap. The methods of softening hard waters have been explained on p. 639. Rain-water properly purified would be extremely useful for cleansing purposes, where the domestic supply was of hard water. The mere act of boiling water softens it (p. 639), and thus hard water used for hot baths will be less disadvantageous than if the water were used cold. But a suggestion has been made by which, by simple and not expensive means, a supply of distilled water for washing purposes might readily be obtained in every house provided with a hot-water boiler. Such boilers are all provided with a pipe by which the steam blows off. This usually discharges into the open air. If this pipe were made in a spiral form, carried through a small tank of cold water and then made to open into a cistern, the steam would be condensed and caught as distilled water in the cistern, from which it could be drawn off as required.

Soap is prepared by boiling fat, derived from the ox or sheep and vegetable substances, with caustic-soda solution, a hard soap being thus produced; soft soap is the product of boiling fat with caustic potash. The oil from the olive mixed with other vegetable oils is used for Castile soap, the white variety of which is one of the most excellent and soothing quality. Palm-oil, cocoa-nut oil, and other vegetable oils are used for the same purpose. Curd soap, when pure, is made from tallow and soda only, and is of good quality. Curd soap and palm-oil soap are the usual basis of most toilet soaps, to which a proportion of glycerine may be added, in the glycerine soaps, and to which also colouring matters and various perfumes are added. Some colouring agents are injurious; red and magenta colours should be avoided, the red colour being sometimes derived from a mercury or lead preparation, and the magenta colouring matter being liable to contamination with arsenic. The safest soaps to use for the skin are the pure white curd or Castile soaps, and the transparent soaps of makers of repute. The transparent soaps are less likely to be adulterated than others, since adulteration would interfere with their clearness. An excess of soap will unduly soften the skin, owing to the action of the soda, and therefore the smallest quantity that is suitable should be employed, and very thoroughly washed off afterwards with water. None should be left for removal by the towel.

The use of the hands is to be preferred to sponges, flannel cloths &c., for the fingers can more effectually insinuate themselves into the folds of the skin and the due amount of pressure can be better regulated. The friction of the hand is also pleasantly stimulating to the skin.

The bath, however, serves other purposes than those of cleansing, though none more valuable. The hot bath relaxes the blood-vessels of the surface and causes a freer circulation in the skin. If more blood flows to the skin there is, of necessity, less in deeper organs, which are consequently relieved, and a soothing and calming effect is thus produced. None of the organs of the body experiences such effects more markedly than the nervous system, and the effect of the hot bath in inducing sleep is thus explained. The cold bath, on the other hand, drives the blood to the deeper parts and promotes their activity, though, if the cold be not too prolonged, reaction sets in when it is over, blood flows more freely to the skin, and a general stimulating effect is produced. For such reasons the evening, before retiring to rest, is the most suitable time for the warm bath, and the morning after rising for the cold bath, the former conducing to rest, the latter to activity. Various methods are employed for concentrating the action of one or other on special parts or organs of the body, such as by the hip or sitz bath, douch and needle baths and so on, which will be considered in a little more detail. Thus baths are made use of not only for the ordinary purposes of health, but also for the treatment of disordered states of the body, their value for which has been recognized only in recent years.

Too frequent bathing of the skin, whether of one part or of the whole surface is not commended, specially if each time soap is employed. The oily matter produced by the sebaceous glands is designed to oil the skin and keep it soft and pliable. If it is too frequently removed, the skin becomes too dry and is prone

to crack or chap. Other consequences may ensue from the skin being irritated by the excessive stimulation, such as the production of eruptions and so on. The skin of some is much more susceptible to such influences than that of others. For example some can scarcely use soap to the face, because of the irritation it induces. In such cases the addition to the water used of a few drops of weak ammonia, spirits of hartshorn, or a tea-spoonful of sal volatile, will effect the removal of oily matter from the surface without irritation.

Varieties of Baths.—The temperature of the various kinds of baths is given in the following table:

Cold Bath	50° to	70°	Fahrenheit.
Tepid ,,	85° ,,	95°	,,
Warm ,,	96° ,,	104°	,,
Vapour ,,	96° ,,	110°	,,
Hot ,,	102° ,,	110°	,,
Very hot ,,	110° ,,	120°	,,
Hot-air[1] ,,	175° ,,	212°	,,

The Cold Bath.—The first effect of the cold bath is to produce a shock on the nerves of the skin. As a result the vessels of the skin become strongly contracted, the blood is driven out of them and seeks the deeper parts, which also will be suddenly excited by the rush of blood to them. Proof of this is found in the increased rate of the heart's beat and the quickening of the breathing. The temperature of the skin is reduced, but not that of the body as a whole, unless the immersion be prolonged. Indeed at first the internal production of heat is quickened by the stimulus to the internal organs. If, however, the application of the cold be prolonged the temperature of the body will be lowered, because water is a conductor of heat, and heat will be removed from the body more quickly than it is produced. For such a purpose cold baths are largely employed in Germany in cases of fever. The prolonged action produces depression, the action of the heart becoming feebler and slower, due to the action of the cold upon the nervous system as well as to the direct abstraction of heat. For recovery from such depression artificial aid, in the shape of hot blankets &c. and stimulants might be necessary. But in the case of the cold bath as ordinarily used, the application is short, and the more near to the temperature of 50° Fahr. the water is the shorter must it be. Following the first action is reaction, during which the blood returns to the skin, the blood-vessels of which relax, and a pleasant sensation of "glow," spreading rapidly over the surface, is experienced. This reaction is aided by rapid friction of the skin, as by towels, and if, after drying, the body is quickly clothed and exercise engaged in, the total effect of the bath is stimulating, inducing a feeling not only of warmth but also of vigour. The markedly stimulating effect on the various organs of the body is shown by the fact that the amount of carbonic acid gas given off from the lungs and of urea from the kidneys is increased, indicating increased tissue change, evidenced also by increased appetite. The length of time the cold may be applied without interfering with the setting in of a proper reaction depends upon the individual. A mere instant's immersion is sufficient for some, others can bear several minutes, while some could not bear complete immersion of the body at all, a feeling of coldness and shivering lasting for hours after it. Obviously for such persons the full cold bath is not suitable, but that does not necessarily imply that the use of cold water to the body is to them hurtful in every form. Much depends on habit, and a person unaccustomed to the full cold bath is not likely to find it pleasant without some preparation for it. This preparation can be given by the use of the cold wet towel &c. for some time, gradually leading up to the full cold plunge, which may thus be made tolerable and enjoyable.

The cold bath is not suitable for the old and the delicate. The shock is too great, and a proper reaction does not set in. Besides in delicate persons the rush of blood to the deeper organs may produce too great a strain upon weak parts. Of course old persons who have been accustomed all their lives to the cold bath need not break it off, if it continues to agree with them, or they may simply modify it by using some of the milder forms to be noted.

The action of cold may be intensified by pouring the water upon the body from a height, by causing it to fall upon the body with force as from a hose, or by showering it or spraying it on the body by the use of various arrangements of pipes &c.

The morning or early part of the day is the suitable time for such kinds of baths. Persons who are thus habituated to the use of cold water are less susceptible to the influence of cold and can stand longer exposure than others.

The Wet Sponge is the mildest method of using cold water, and is well adapted for the weak and delicate. The body may simply be

[1] This degree of temperature is of course unbearable unless the air is dry, and the explanation of its being borne is given on p. 735.

rapidly sponged over, or the person may stand or sit in a large shallow bath, and the water be squeezed from a sponge over the shoulders and body. This may be done in a warm room, the water in which the person stands being warmer than that from the sponge. After one application of the cold water, the person is quickly dried and dressed. At first the water in which the sponge is dipped should be tepid, and day after day may be used colder, as the person becomes accustomed to it, till quite cold water is used.

The Wet Towel is not quite so mild as the sponge. The towel is dipped in water of the desired degree of coldness, wrung lightly out and applied to the body, which is then vigorously rubbed with it.

The Wet Sheet is still less mild. The whole body is enveloped by the sheet, and rubbed up and down for several minutes. The wet sponge, wet towel, and wet sheet, may be used as stages in accustoming the body to the employment of cold water, preparatory to the trial of the ordinary cold bath; and the degree of coldness of the water and length of time of application can be regulated according to the effects produced.

Tepid Baths produce neither depression nor excitement, and are therefore suited for all. They are the best when prolonged immersion is desired, as in the treatment of chronic skin and nervous diseases.

The Warm Bath is particularly serviceable in removing feelings of fatigue. It should quicken only slightly the circulation, and bring an additional quantity of blood to the skin. It is by this means that it removes the tired feeling from exhausted muscles, for it promotes the removal from the tissues of the waste products, which have accumulated during the period of activity, whose presence in the muscles is the cause of the feeling of weariness. After prolonged labour, or a long fatiguing walk, or prolonged exposure to damp and cold, or after, for example, the exertion of much dancing, nothing is so restorative and refreshing as a warm bath. After such exertion many persons are restless, and desiring repose cannot find it owing to sheer weariness. A full warm bath, prolonged for fifteen or twenty minutes, will remove the ache from the muscles and substitute a feeling of quietness conducive to sleep. It is also capable of restoring the body to a condition in which renewed activity is possible with comfort. When employed for such purposes, the person should end with a spray or douche, or simple sponge of tepid water (70°) if he is about to go to bed, or with a warm spray, quickly reduced to cold, before dressing to go out.

Warm baths are largely employed in feverish affections of children, for promoting the action of the skin; and they are a safe resort in the convulsions of children, cold being at the same time applied to the head.

The Hot Bath acts in a more pronounced way upon the heart and nervous system than the merely warm bath. If very hot it powerfully excites the heart, whose action, indeed, it may stimulate to violence. The brain is also influenced by the more copious flow of blood through it, due to the vigorous action of the heart. These effects, however, are largely counterbalanced by the increased flow of blood to the skin. But the prolonged use of hot baths is weakening, and the temporary strain thrown upon the heart and blood-vessels and brain would be hurtful to many. The bather should be immersed to the chin; the hair is damped with cold water, and a thin cold cloth is wrapped about the head. Cold water may be drunk if desired. The bath should last twenty minutes, or less if oppression is felt. It should conclude, as directed for warm bath, with tepid douche or sponging, or with warm spray quickly reduced to cold. The hot bath should not be used in the morning or early part of the day, or at any time except before going to bed, unless the person is properly cooled down before dressing and going out.

Warm baths are valuable means of reducing excitement, and relaxing spasm, such as the temporary spasm causing inability to empty the bladder.

The Hot-air Bath is one of the most powerful ways of stimulating the activity of the skin. The person, unclothed, is placed in an apartment heated by means of furnaces, the air being dry. In a longer or shorter time, according to the heat of the air and the condition of the bather, the perspiration bursts out upon the skin, becoming very copious, so that the whole body is bathed in sweat. A very high temperature may be borne so long as the air is quite dry, for the sweat passes rapidly off from the body in the form of vapour, removing a large quantity of heat, and thus the temperature of the body does not rise, unless the air is very hot, when the heat of the body usually increases by two or three degrees. The same high temperature could not be borne if the air were moist, as in the case of a vapour bath, for then the air is saturated or nearly so with moisture and cannot take up more, or can take up very little.

In this case the sweat does not readily pass off from the body, and the regulating action of the skin on the heat of the body is interfered with. Marked oppression, difficulty of breathing, fulness in the head, faintness &c. would then speedily arise. When the air is quite dry, however, a high temperature, for example, that of 180° Fahr. can usually be endured with ease, and even above 212°. Not only the activity of the skin, but the action of the heart and of breathing are greatly increased. It is thus not suited for everyone, certainly not in its full form for anyone with weak heart or vessels, and for very full-blooded persons. The hot-air bath may also be given in a box heated with gas or spirit-lamps.

The Turkish Bath.—The hot-air bath is usually obtained with other accessories in the form of the Turkish bath. This bath was adopted by the Turks from the Romans, who derived it from the Greeks. The ordinary method, as used in this country, is well known, and the general arrangements need be but briefly mentioned. The bather enters the dressing-room (Roman *Vestiarium*) which is heated to an ordinarily comfortable temperature. Round the wall are stalls, curtained in front, and each provided with a couch. Beyond this room there are, in the fully-equipped Turkish baths, three rooms, separated from the dressing-room by well-padded doors. The first of these corresponds to the Roman *Tepidarium*, the warm room, in which the temperature is from 115° to 120°; beyond this and separated from it by heavy curtains is the hot room, or *Calidarium*, in which the temperature ranges from 120° to 140°; and still beyond is the hottest room, called also the flue room, corresponding to the Roman *Laconicum*. Here the temperature is not below 150°, usually 175° to 180°, but may be 200° and upwards. Every Turkish bath has certainly two rooms beyond the dressing-room, one in which the temperature may readily be raised to 140° or thereby, and one beyond it in which the highest temperatures may be obtained. The heating is accomplished by flues, beneath the flue-room, the other rooms being heated from it as well as by means of heated fresh air, admitted through appropriate openings. The flue from the furnace passes underneath the floor of the hottest room, and enters a coil of cast-iron pipes, coiling along three sides of the room, the walls of which are formed of glazed brickwork.

A most important point in the construction of a Turkish bath is the arrangement for ventilation. The great rapidity with which evaporation takes place from the body, subject to the high temperature of dry air, would speedily cause the atmosphere of the rooms to be impregnated with emanations from the skin, which would be inhaled by the bathers unless some very efficient means existed of removing the polluted air and substituting fresh warm air. This is of vital importance, and is necessary also for another reason, namely that the evaporation of sweat from the body renders the atmosphere moist. Now the air of the Turkish bath ought to be perfectly dry, and therefore the continual removal of moist and polluted air and its replacement by perfectly dry and pure hot air are necessary. This is now accomplished, in the best baths, by utilizing the draught in the exhaust flue of the furnace. The foul air is drawn *from the floor*, for it is near the floor the foul air collects, since it is less warm than the entering hot air, and is heavier by reason of the moisture and impurities it contains, and passing through pipes along the side of the bath reaches the chimney. Any arrangement which seeks to ventilate from the roof defeats its own ends, since the fresh hot air rises and will be drawn off, while the polluted air will be left.

In the warm rooms the bather reclines on a zigzag wooden chair, over which he spreads his dry bath-towel. In the hottest room the floors require strips of matting, or felt slippers are worn, to protect the feet. Wooden chairs are not admissible, on account of the great heat, and the best form of chair is one with canvas seat and back, which are easily cleaned by washing.

Convenient to the warm rooms is an apartment moderately heated and provided with low tables of marble, corresponding to the Roman *Lavatorium*. On one of these the bather lies down and is rubbed or shampooed by the bath attendant, soaped and scrubbed, and finally douched first with warm and afterwards with cold water, preparatory to a return to the dressing-room, as described later.

These being the general details of a Turkish-bath house, it will be well to describe the regular course of the bath itself; and we shall first of all describe the full bath as taken by anyone with whom time is no consideration, in a bath with three rooms of increasing heat.

The Full Bath.—The bather undresses in one of the curtained recesses of the dressing-room, girds a towel or similar contrivance round his loins, and carrying a bath-towel over the arm passes into the warm room. Here he stays only long enough to wet the hair with cold water, and perhaps drink of it, and then passes

on, straight through the hot room, into the hottest room. Spreading his towel over a chair he reclines upon it, talking little or not at all, wets his head with cold water, and drinks at his pleasure, but not too copiously, of cold water, which the attendant will bring him. Here he remains five or ten minutes. By this time the whole body will be bedewed with perspiration; and the bather passes out into the room next in temperature, the hot room, where he reclines for another ten or fifteen minutes. Then he passes to the warm room, lower in temperature than the former, and here he reclines till the attendant is ready for him, when he proceeds to the washing room. Here he lies on a table and the attendant goes over the whole body, rubbing the surface, and thus removing all loose effete skin, grasping and kneading muscles, bending joints and so on. He is then rubbed over with soap, scrubbed and washed down, and lastly douched with warm and then tepid and cold water. From this room the bather passes out quickly, plunges through a cold bath, and regains the dressing-room, where he is quickly dried down with warm dry towels. He is then enveloped in a dry bath-towel, and so attired he lies down on his couch in the dressing-room, covered over with a light rug or blanket, till his skin assumes its natural degree of warmth. Here the soothing influence of the bath proclaims itself, by the tendency to sleep which it induces, which should not be yielded to, however, because of its relaxing effect. When the skin is cool and dry, usually in fifteen or twenty minutes, the bather dresses quietly and deliberately. It is important that he should rest a sufficient time to be quite cooled down before he dresses, lest a second perspiration be induced as soon as he walks abroad, leading to a chill. At the same time he must not rest so long as to become chilly. Each bather should be able to determine by his own sensations, when is a suitable time to dress. Employed in such a way as has been described, the Turkish bath is not only unexcelled for its purifying effects, but is a wonderful restorative after fatigue, and imparts a delightful sense of lightness and buoyancy.

Now it may be pointed out that this order of taking the different rooms, the hottest first, and thereafter those of a lower temperature, is advised because a few minutes of the dry air of the hottest room will bring out the perspiration, as a rule, quickly, and will thus speedily relieve the strain on the heart and other organs. Once the perspiration is fully out it is easily kept up by a lower temperature, and hence the return to the room of lower temperature does not arrest it. On the other hand if one stays in the hot room till the perspiration is well out, and thence passes to the hottest room, a drying effect is apt to be produced. In the hot rooms the temperature of the body rises, one or two degrees, till the perspiration breaks out, by the evaporation of which it is prevented rising higher.

Taking the order of the bath as has been here given, many people entertain considerably divergent views as to the degree of heat that is desirable in the hottest or flue room, some being unsatisfied if 200° or even 212° is not reached, others seeking to have it about 175°, and others still lower. Concerning this point Dr. W. B. Hunter, of Matlock, makes the following remarks:—"It is no exaggeration to declare that the customary practice of a public bath has for its aim and ideal the endurance of the greatest possible temperature for the longest possible time. This is a truly simple ideal, and there is a certain simplicity likewise in those who strive after it. The result, on the contrary, is otherwise, and to such as are not gifted with an exceptional constitution and superabundance of vitality, the strain it involves brings much of mischief along with the benefits inherent to the bath. It entails in time an enfeeblement as marked as that invigoration which a more moderate use of the bath most surely affords.

"With the thermometer no higher than 103°, when one foot only from the floor level (at the customary height of five feet it was 115°), a copious perspiration was maintained for a period of forty minutes. The pulse meanwhile was soft, and never got above 84 beats per minute; the respiration was quiet and stood at 12½ per minute throughout, and the heat of the body, as observed by a clinical thermometer, kept close from beginning to end in the axilla (armpit) never got above 98·6°, an elevation no more than two-tenths of a degree beyond the normal. This should serve to show how little may be necessary, after all, for attaining to the full the principal object the bather has in view, and how slight need be the strain involved in its maintenance—an irreducible minimum, it might fairly be called. While recording these observations, note was made at the same time of the lot of a fellow experimenter who took his place in an adjoining room where the temperature registered as high as 156° though fixed but one foot above the floor level. The limits of physical endurance were reached with him in the space of twenty-five minutes only, whilst, with

no greater evidence of perspiration at any stage than was forthcoming at the modest temperature aforementioned, the pulse had gone up to 116, the respirations to 21, and the bodily heat to 103°. The palpitation, giddiness, and prostration, which thereupon compelled his retreat to the cooler chamber, subsided almost at once, and the pulse fell immediately to 102. Both experimenters were fairly representative, because habituated to the use of the Turkish bath; and subsequent observations were, in every point, confirmatory of this one. An extensive acquaintance with the bath in almost every variety of case and constitution has led the writer to adopt 135°, the thermometer standing at a level of 3 feet, as the maximum temperature proper for ordinary use in the average subject. From 115° to 120° is the temperature proper for the feebler order of patient, the hyper-sensitive also, and as the first or introductory bath for such as are not unmistakably robust, and free from the suspicion of anticipatory nervousness. For the regular *habitués* of public baths, on the other hand, an initial temperature of 170° is at worst but a harmless indulgence, provided it be not endured beyond the bounds of comfort, and is exchanged at once for a lower, as rational observation may suggest."

"That there are some who find themselves equal to encountering much higher temperatures than this, for a time, is not to be denied, but that such powers of endurance are exceptional, and the occasion for their exercise more exceptional still, is the teaching of experience to one whose opportunities of noting results have not been limited to a few cases, nor to the immediate occasion."

The ordinary duration of the full bath, from the flue room to the washing room, is from forty minutes to an hour. The time may be curtailed thus: flue room five minutes, hot room fifteen minutes, warm room ten minutes, and the remainder as directed.

Various modifications may be introduced. If the bath be taken only occasionally, the shampooing and soaping are desirable thoroughly to cleanse and stimulate the skin. If it be taken more frequently, as in a course of the baths, the shampooing and soaping may be dispensed with, except once or twice a week, and from the warm room one may pass to the washing room merely to be sluiced and douched. Again, after the washing, one may have a warm followed by a cold douche, and then pass straight to the dressing-room, without the cold plunge.

The full bath, however, though slightly modified in this way, is suited chiefly for those accustomed to it, and for the healthy and robust. For those, unaccustomed to it, a briefer form of bath is preferable as a preparation, for the first one or two occasions, and may be the only advisable form for those not quite robust.

The **Brief Turkish Bath** begins with the hot room, not the hottest or flue room, where the bather stays for ten minutes or thereby. The warm room is then entered for other ten minutes, and thereafter the bather proceeds to the washing room, ending as already described.

Many bathers never use the hottest room at all, remaining in the hot room twenty-five minutes or more or until profuse perspiration is excited, and passing through the remainder as described.

The **Mild Bath** consists in spending twenty to thirty minutes in the warm room only, thence the bather passes to the washing room. This is the form for the very old, the very young, and for invalids.

Some persons do not readily sweat in the warm room. If so they should not enter the very hot room. At first at least they should be content with the warm room, and after several trials the skin may be got to act more fully, when the very hot room may be borne. Difficulty in perspiring is held to be an indication for the need of the Turkish bath, rather than the reverse, an indication that the skin is not discharging its functions duly, and that this, the most powerful means of re-establishing it, will be followed by specially beneficial effects. When any real difficulty exists, an expert attendant is likely to be able to overcome it, if necessary by the use of a hot soaping bath for a day or two, or other means.

The Vapour Bath acts upon the body much as the hot-water bath does, but it acts more powerfully, though the effect of the heat is not so quick since vapour is a slower conductor of heat than water. This bath can, therefore, be borne hotter than a water bath, but the high temperature cannot be borne long, for the vapour does not permit of the loss of heat from the body as hot air does. The temperature of the vapour bath cannot be comfortably endured above 120° Fahr. The vapour bath is characteristic of the Russian baths. It is taken in a chamber filled with vapour, which is thus not only applied to the surface of the body but also inhaled. This makes it still more oppressive. It may be used, however, in a simple form, in which the vapour is not breathed, by the person sitting on a chair, inclosed within a box, an opening in the lid of

which permits the head being outside. This form of bath can readily be improvised anywhere. It is only necessary to seat the person naked on a chair, and surround him from the neck downwards by blankets, which envelop the chair also and hang to the ground. Under the chair is placed a shallow earthenware or metal dish, containing boiling water to the depth of 3 or 4 inches. Into the water are placed a couple of red-hot bricks. Or under the chair may be placed a spirit-lamp, supported above it being a shallow pan containing boiling water. A simple apparatus for such baths is in the market. Such baths are very useful for catarrh, for rheumatic and neuralgic pains, sciatica &c., as well as for cases where excessive action of the skin is desired to relieve deeper organs, for example the kidneys.—Ten to fifteen minutes are long enough for exposure in the vapour bath.

Sea-bathing.—Ordinary sea-bathing is of course cold, and produces the stimulating effects which have been described in the paragraphs devoted to the cold bath. There is besides the additional stimulus due to the salt, so that sea-bathing acts as an invigorating tonic. It is not, however, suited for everyone, and is taken much too indiscriminately. It is also indulged in without due precaution. It is a very common error for persons to remain in the sea too long. The townsman, as soon as he gets to the watering-place for his well-earned holiday, hastens to take a swim; and, if he is in company, thinks he ought to remain in the water as long as his companions, who, it may be, have been regular bathers for some time previously. He is somewhat disgusted on coming out to find himself shivering, and to notice the blueness of his skin, finds it difficult to get on and arrange his dress, because of stiff fingers, and cannot readily get up heat again, while his companions are glowing with warmth and vigour. He has stayed too long; depression has occurred and reaction is slow to set in. He may be giddy and threatened with headache, from excess of blood to the head. He is prone to conclude, or his companions to conclude for him, that sea-bathing does not suit him, and perhaps he is tempted to give it up. The proper course is for him next day to greatly shorten the length of his stay in the water. He ought simply to plunge in, come out quickly, and after a vigorous rub dress rapidly. Next day this may be repeated. If he finds reaction now readily sets in, he may prolong his bath by a minute the succeeding day, and thus gradually accustom his body to the bath, till he can equal his companions in the length of the bathe. Persons who are anæmic—that is, of deficient quality of blood—ought not to indulge in sea-bathing without advice, and failing advice had better try first a salt-water bath at home. Persons who have suffered from any internal complaint ought also to refrain.

The best time for sea-bathing is in the morning. It should never be indulged in immediately after a meal, when the business of digestion is going actively forward. Indigestion, cramp in the stomach, headache and so on are almost certain to ensue. If it be not taken before breakfast, a good time is before lunch or early dinner, for which the brisk walk home after the bathe will prove an excellent appetizer. Neither should sea-bathing be engaged in immediately after very active exercise when the body is in a state of very active perspiration or in a condition of fatigue. At the same time, moderate exercise before the bath is unobjectionable, and the body ought to be comfortably warm. The person should not wait till he has become perceptibly cool, but should undress quickly and plunge in bodily, wetting the whole body at once. Wading in to deep water is undesirable, the distribution of blood being upset by the cold water driving it upwards as one advances to deeper water. During the bath exercise should be active, as in continued swimming.

It should be remembered that children, because of the little-resisting power of their young bodies, are very readily depressed by sea-bathing, and are not to be subjected to it as a matter of course. By bathing at home, by wading, which they usually enjoy, they may be gradually accustomed to it; but they ought not to be forcibly immersed to their aversion and terror.

Sea baths may be imitated at home by the addition of common salt or sea salt to water. About 9 lbs. of salt to 30 gallons of water is a quantity commonly used. These are useful for children and specially for such as are of a scrofulous habit of body. For such sea-water is also used at home, after being warmed to any required degree.

River-bathing is less stimulating than sea-bathing because of the absence of the saline constituents of the water. The general rules applicable to sea-bathing are applicable to such fresh-water baths.

The benefits of open-air bathing—sea or river—are not limited, of course, to the action of the water but are increased by the action of the fresh air, the respiration of which is stimulated

by the bath, and by the active exercise in the open air invariably indulged in afterwards.

Medicated Baths.—There are many kinds of baths which have, or are supposed to have, special properties, valuable for diseased conditions, because of containing various saline substances dissolved in them. Such baths may be artificially prepared by the addition of the salts to the water, or natural mineral waters may be used for the purpose. Thus there is the **alkaline bath**, made by adding 6 ounces of crystallized carbonate of soda or 3 ounces of carbonate of potash to 25 or 30 gallons of water, a very useful bath in irritable diseases of the skin, such as itching, eczema &c. There is the **sulphur bath**, made by dissolving 4 to 8 ounces of sulphuret of potassium in 25 to 30 gallons of water, also useful in skin affections. **Pine baths** are made by adding some of the pine extract to the bath water. Extract made from the leaves of the pine is made and sold for this purpose, about a pound being the quantity added. A recent preparation—the extract of pumiline pine—is used for a similar purpose. They are employed in gouty and rheumatic cases and also for irritable conditions of the skin.

The **Mustard-bath** is made by adding a handful or more of mustard to the ordinary warm bath. It is seldom, however, used for a full bath, but is mainly employed as a foot-bath, for which one or two tea-spoonfuls of mustard are sufficient. The mustard foot-bath is a favourite and useful domestic method for warding off the effects of cold, combined with a hot drink and a warm bed. It is an exceedingly speedy method of withdrawing blood from other parts of the body. It will wonderfully relieve the throbbing headache of the congestive kind, and it may quite safely be used in the convulsions of children, their legs being dipped into it, and kept there till the skin is quite red.

It is not necessary to enumerate the various natural mineral waters, which are used for bathing purposes as well as for internal consumption. Some of them are considered in the sections devoted to drugs. It is only necessary to recall what has been said on p. 310 in reference to the very slight power possessed by the skin of absorbing substances. Any influence medicated baths are likely to have is not, therefore, due to the contained salts passing into the circulation, but to the temperature of the water, and the remote effects on nerves, heart, breathing &c. that, as already explained at the beginning of these paragraphs, may be so induced, and to the local effects on the skin, which will undoubtedly be influenced by the substances the waters contain in solution.

Mud-baths made of a muddy kind of earth found specially at Franzenbad in Bohemia, and used also at Carlsbad and Marienbad, also in Bohemia, are found useful in irritable conditions of skin, as well as in conditions of nervous excitement and in rheumatic affections. The earth is mixed with water from the mineral spring till it is throughout of a soft poultice-like consistence, a bath-tub is then filled with it, in which the patient sits, up to the neck, for about twenty minutes, after which the mud is removed by a clean water bath.

Various arrangements are employed for accentuating the effect of the water, whether used hot or cold, or for applying it to particular parts of the body.

The Douche is a jet of water directed upon some part of the body through a 1½-inch pipe, the force of the water, quantity discharged, and temperature being capable of modification. It at first lowers the vitality of the part to which it is applied, but reaction sets in quickly, so that its whole effect is stimulating, quickening tissue change. The douche may be used hot or cold, or one after the other in rapid succession, a change which is most stimulating of all. In old-standing complaints, thickenings about joints, for stiff joints &c. it is a very useful application. In the case of the descending douche, the pipe is 10 to 15 feet above the floor level, and for the horizontal douche the pipe is 4 feet above floor level. In the former case it is played first on the spine, and then shoulders, hips, arms and legs in succession. At the close it is directed on to the chest and head, the force of the water being broken by the hands. In the latter case the back, chest, arms, and legs are douched in the order named, while the patient rubs himself vigorously. Before beginning the head is wetted with cold water, and is douched last, the force of the water being broken.—The process should last from one to two minutes.

The Spray may be used hot (100° Fahr.) for half a minute, and then gradually becomes cold for two or three minutes, while the patient turns round, rubbing himself vigorously, the head getting its share. If used simply warm (90° Fahr.) and reduced to tepid (70° F.) slowly, it is milder. The **Rain-bath** is an overhead spray, and is used as described for the latter. The **Ascending Spray**, as a stimulant to the lower bowel, may be used cold for half a minute, or tepid for one or two minutes, or beginning

warm and becoming as hot as can be borne (105° to 120°) for two or three minutes, or hot and cold alternately, beginning warm (90°) gradually raised as hot as is bearable, then gradually reduced to cold, and raised again to be reduced once more, during a period of four minutes.

The Needle-bath is simply a fine shower-bath, arranged circularly so that the fine streams of water converge upon the body, the multitude of fine streams having a more stimulating effect than a simple dash of a mass of water would have.

The Sitz-bath or **Hip-bath** is a means of limiting the application of the water to the hips, buttocks and neighbouring parts. The form of the bathing-tub is such that the person has the bath in the sitting posture, the limbs and upper part of the body being out of the bath. When used as hot as can be borne, the bath is half filled with water at 100°. The patient sits down in it, on a hot flannel pad, another being placed on the back of the bath, the feet, outside of the sitz-bath, being immersed in a foot-bath of water at the same temperature. The patient is then enveloped in warm blankets from the neck, a thin cloth, wetted with cold water, being tightly wrapped round the head. After a few minutes, a pint or so of boiling water is poured slowly against the side of the bath, and this is continued from time to time till the water is as hot as can be borne (110° to 120°), sufficient water from the middle of the bath being removed to keep the level of water an inch below the bath brim. In twenty minutes the patient stands up and is sponged over with water at 80°. The cold sitz-bath should last only two or three minutes.

The sitz-bath, hot or cold according to circumstances, is in much use for abdominal and liver complaints, and specially for feminine ailments. Its soothing effects, when used hot, in painful and spasmodic disorders of bowels, bladder, and womb, are very marked.

The **Full Pack** is directed to be given as follows: On a bed or packing couch spread lengthwise three blankets, large and thick; and upon these a thin linen sheet wrung well out of cold water, its upper margin folded short of that of the blankets by half a foot or so. The patient lies down undressed on the sheet with arms close to sides, the head just beyond the upper margin of the sheet, the feet well within the lower, and so wrapped up in it quickly, one side after another, the neck and feet with special care. The blankets next, each in turn, are, side after side, tucked round about and beneath the body, smoothly and lightly, the spare blanket beyond the feet doubled back beneath. On the top of all put the bed-clothes, lightly pushing them under on each side, and lay the pillows, one lengthways on the body, the other across the legs, leaving the bolster alone beneath the head. Put a cold wet cloth round the head, a hot-water bottle to the feet, and give cold water to drink as desired. The window should then be opened—there being nothing in the case to the contrary—and sleep favoured. Let the patient remain thus for one hour. If the hot pack is given, the sheet is wrung out of boiling water, and kept coiled up till required.

This form of bath is a gentle but very efficient method of stimulating the skin and producing perspiration. It is in much use in feverish complaints, and is very valuable in "determining to the skin" in eruptive diseases like measles or scarlet fever. For calming excitement and restlessness, and inducing sleep it is also exceedingly useful; and it affords marked relief to the kidneys.

The Use of Baths in Disease.—The value of baths of various kinds in disease has been alluded to, by the way, in the preceding paragraphs. As an agent in the maintenance of health the bath is a necessity. As a means of restoring vigorous health to those who, without being the subjects of any actual disease, are yet "down" in general health, as the result of prolonged overwork, anxiety &c., it is an agent of great power. The stimulating and invigorating action of the cold bath has been sufficiently spoken of, and the soothing and sleep-persuading effects of judiciously-given warm baths have also been referred to. The treatment of actual diseased conditions by baths in association with rational treatment by medicines is an art requiring the knowledge and discretion of the skilled physician, applied to each particular case, and it is not, therefore, possible to state here rules, which can take the place of such active superintendence. It may be noted, however, that rheumatic and gouty disorders, chronic affections of the skin, digestive derangements, especially such as are associated with sluggish conditions of the abdominal organs (sluggish liver, constipation &c.), are among those in which the treatment by baths yields the most surprising and gratifying results.

In particular the Turkish bath, when administered not at random but under skilled superintendence, and in a degree suited to the strength and age of the person, is fitted to produce results far more effective than is generally

recognized. The reason is quite readily understood. These diseases are mainly those of bad general nutrition, dependent to a large extent on a bad quality of blood or to a bad distribution of blood. The free stimulation of the skin, which is produced, not only rids the blood directly of much effete material, which, in the case of gout and rheumatism, is at the bottom of the disorder, but also indirectly by the secondary effect on the other organs for removing waste, such as liver and kidneys. The improved condition of blood which results will profoundly affect every organ and tissue of the body. Similarly the redistribution of blood will relieve organs unduly charged with blood, and will induce a better supply to others which formerly enjoyed too little. Engorged conditions of liver and kidneys, catarrhal states of the air-passages, as in bronchitis, of the urinary passages, and of stomach and bowels, are markedly benefited by such changes. The effect of the withdrawal from the blood of the large quantity of water, which occurs during the exposure to the dry hot air of the bath, is found to be markedly beneficial in cases where there is an accumulation of fluid in some of the cavities of the body, as in the various forms of dropsy, while the absorbent system of vessels is also stimulated to the removal of the results of inflammatory swellings and thickenings. Nervous disorders, hysteria, neuralgia, nervous headache, sleeplessness, and so on, ought to be greatly influenced by a judicious use of such baths. Especially will this be so, if to the calming effect, produced by the withdrawal of blood from the central nervous organs to the skin, there be added the bracing and tonic effects of the spray, douche, &c., hot and cold, as may be appropriate to the case, combined with the powerful stimulus to improved nutrition which can be brought to bear by massage.

In particular it ought to be noted by anyone, to whom a Turkish bath is easily accessible, that it is of signal service in simple chills. At the outset of an ordinary cold, it will often prove an effective check, as well as to the ordinary stomach and liver disturbance, common to many as the result of cold.

While anyone may resort to the Turkish bath, at his own discretion, to ward off the effects of a suspected chill, or to cut short a simple cold, it should not be indiscriminately tried, it must again be said, for the graver disorders of lungs, kidneys, &c. For these cases competent advice and supervision should always be sought.

The value of the hot or cold bath, and similar substitutes for the Turkish bath, in eruptive fevers, has already been remarked on. On the Continent cold baths for the reduction of high temperature, specially in typhoid fever, are in extensive use.

Is the Turkish bath not weakening? is a question one hears very often put in a tone of voice that implies little doubt that it is so. If the explanations that have been offered as to the action of the bath have been understood, one will be prepared for the answer that, instead of being weakening, it is invigorating, *when properly employed.* If a man be weighed immediately after a Turkish bath, he will have lost weight undoubtedly, by the quantity of water and its dissolved salts, &c., and the amount of carbonic acid gas, &c., that have escaped from his skin and lungs—water and waste products, that is to say. The loss of water is easily made good, if that be necessary. The temporary loss of weight is a mere incident, however; the real and essential results are the quickened circulation, the redistribution of blood to the various parts of the body, the stimulation of various organs, and the sweeping out of the body of effete and hurtful materials. The results of these changes are speedily apparent in a feeling of freshness and lightness, and within a few days in increased appetite, because of improved digestion and absorption of food. This is the explanation of the fact that within a few days of commencing a course of baths, a person begins actually to add to his weight and to be aware of increased bodily vigour, provided appropriate food and exercise have reinforced the action of the bath. As a matter of fact repeated weighing is made use of in the best-conducted baths as an indication of the effects being produced. In cases of corpulence, of course, loss of weight is desired, but it is loss of weight by reduction of fat only, not by reduction of muscle. Indeed the corpulent patient needs not only to lose fat, but, as a rule, also to *build up* muscle. This process, also, the bath will aid, but, again, only when associated with proper dieting and exercise. In such cases it promotes the loss of weight in the same way that in others it promotes a gain of weight, namely by restoring the normal process of healthy nutrition, enfeebled in the latter class of cases and perverted in the former.

SECTION VI.—EXERCISE.

Effects of Exercise:
Effects of Exercise on Muscles;
Effects on the Heart and Circulation;
Effects on the Breathing;
Effects on the Digestive Organs, on the Skin and Kidneys;
Effects on the Nervous System.
Excessive and Defective Exercise.
Various Forms of Exercise:
Walking—The Expenditure of Energy involved in Walking and Climbing—Proper Daily Amount of Walking—Exercise for Girls and Children;
Running—Training for Running;
Jumping;
Rowing;
Lawn Tennis;
Bicycling and Tricycling;
Cricket, Football, and Golf;
Gymnastic Exercises:
Exercises without Apparatus—Exercises for arm, head, body, and leg, adapted for children;
Exercises with Dumb-bells, Bar-bells, and Hoops.
Exercises in the Treatment of Disease:
Massage.

Effects of Exercise.—We use the term exercise, as regards the body, to mean the use to which the various organs of the body are put. Thus we speak of exercising the voice, of exercising the brain, of exercising the faculty of reason, or judgment, or imagination, and we speak of exercising the muscles of the body as in walking, running, riding and so on. It is specially in the last sense that it is made use of in the following paragraphs, the use or employment of the muscles, voluntarily, in the various actions by which external work is done, as in walking, &c., the various kinds of manual labour, and in pastimes such as football, tennis, &c. In these exercises we put the various voluntary muscles of the body into action, and we shall best understand how profoundly such action affects the whole body if we consider how such action affects a muscle and what changes are promoted in it thereby.

The structure of voluntary muscle has been described in Pt. I. (Section III. A.), and its chemical constitution and properties have been indicated. We may recall the facts that a muscle consists of a number of fibres of living material in which chemical changes go on, that when the muscular substance is irritated it contracts or shortens itself, and that it may be irritated by a stimulus applied directly to the muscular substance itself, or by the stimulus given to it by the nerve in connection with it, the usual way in which muscle is caused to contract. While it is in a living state the muscular substance is always undergoing chemical changes. These changes are of the nature of oxidation or combustion, for by them oxygen disappears and carbonic acid gas is produced; that is to say, oxygen unites with substances in the muscle containing carbon, the union of the two substances causing the disappearance of oxygen and the appearance of carbonic acid gas. At the same time heat is produced, just as heat results from the union of the carbon of coal or wood with the oxygen of air in a grate (p. 527). When a muscle contracts, these changes are increased, a greater quantity of oxygen is used up, and a greater quantity of carbonic acid gas and heat is the result, and the more active the contraction of muscle is the greater is the increase in these changes. Moreover it has been shown that, as another result of contraction, more water is contained in muscle than is found in a state of rest. Water, we have seen, consists of hydrogen and oxygen, and the meaning of the increase in the quantity of water is that some substances, contained in the muscle, have been made to yield up hydrogen to combine with oxygen. In short, as a result of the activity of the muscle, certain complex chemical compounds have been broken down, and the carbon and oxygen they contained have united with oxygen to yield carbonic acid gas and water. As a result of this process of decomposition other chemical substances are formed, for after contraction the muscular substance is found to be acid, while at rest it is not so, and the acidity is due to the presence of an acid, called paralactic acid, and of free phosphoric acid. These facts are all indications that in an

actively contracting muscle chemical transformations are occurring, by which complex chemical bodies are broken down, of which carbonic acid gas, water, paralactic acid and other substances are the by-products or waste products. These changes can be shown to occur in a muscle separated from the body, in a muscle separated from the body of a newly-killed frog, for example, which can be made to contract for a very considerable time, after its removal, by stimulating with a current of electricity. It has been established by experiments, which it is not necessary to detail here, that such changes can go on not only at the expense of substances *contained in the muscle*, but also at the expense *of the muscular substance itself*. We, therefore, notice these two facts (1) that by exercise a breaking down of material stored up in the muscle and of the muscular tissue itself occurs, implying the necessity for the introduction of new material for repair, and (2) the formation of waste products occurs implying some arrangement for their removal. The fatigue of muscle, meaning a diminished power of contraction or, if excessive, temporary loss of power to contract longer, such, for example, as causes a person, who has taken a very long walk, to feel as if he could hardly move another step, and produces the tired, wearied, and aching sensation in his limbs, fatigue of muscle is due both to this consumption of material, not sufficiently counterbalanced by repair, and to the accumulation of waste products, which have been produced more quickly than they could be removed. It is probable that it is the accumulation of the waste products in particular that causes the tired sensations of fatigued muscles, and that rubbing of the limbs, the use of a hot bath, &c., greatly diminish these feelings because they help the speedy removal from the muscles of the waste substances. In ordinary circumstances material for the repair of wasted muscular substances is brought to the muscle, and the products of waste are removed, by the blood flowing through the muscle. Blood is brought to the muscle by the arteries which supply it, and it carries with it nourishing material for the rebuilding of the broken-down tissue and oxygen to replace that which has disappeared. The blood, after flowing through the muscle passes away by the veins, and it passes away poorer than it was when it came by the amount of nourishing material and of oxygen it has given up for repair, and less pure than when it arrived by the amount of carbonic acid gas and other waste products it carries off with it. This is shown by the fact that the blood—the venous blood—passing away from an active muscle is poorer in oxygen and contains more carbonic acid gas than the blood flowing to the muscle. Further, to meet the demand created by the activity of the muscle the circulation of the blood through it is more active than when it is in a state of rest, and, as another indication of the chemical changes going on, the heat of the blood is increased after its passage through the muscle.

If, instead of limiting our view to the results of the contraction of one muscle, we reflect what must be the consequences of the activity of a large number of muscles, as is necessary for walking, and still more pronounced in running, in cricketing, in boating, &c., we shall begin to realize how great must be the effect upon the whole body by the increased activity of the circulation induced, by the greatly increased demand for nutritive material for repair, by the call for more oxygen to effect the increased chemical changes, by the stimulation of the kidneys, lungs, and skin that subsequently results from the increased waste products thrown into the blood, which it is the business of these organs to remove, and we begin to perceive how it is that the exercise has a marked influence not only on the muscles called into play, but an immediate and stimulating effect upon every other organ of the body. As to the muscles themselves, the effects of exercise, always supposing it not to be excessive, are still greater than have been referred to. It is not only that substances in the muscle have been broken down and cast off, and that new substances have been built up to take their place. The stimulus to nutrition which the exercise has produced affects every part of the muscle, and not only those substances in it or of it, involved in the chemical changes. Every fibre of it shares in the benefits of the increased flow of the nutritious fluid through it, and increased size and vigour of the fibres, and, it may be, the production of new fibres, are directly encouraged. Not only does the movement of the muscle and the quickened flow of blood through it serve to remove the waste matters produced by the activity of the moment, but effete material, formerly produced, whose retention in the muscle has been encouraged by a period of comparative inaction, is now swept out. Thus the muscle is strengthened by the formation of new material in increased amount and reinvigorated by the cleansing process to which it is subjected. On the other hand, if for a season, more or less pro-

longed, little exercise is indulged in, the lessened activity of the muscles implies diminished circulation throughout them, and a falling off in muscular vigour and actual decrease in the bulk of the muscles, through wasting or atrophy. These are illustrations of these facts familiar to every one.

"The smith, a mighty man is he,
With large and sinewy hands;
And the muscles of his brawny arms
Are strong as iron bands."

The relation between the regular methodical use or exercise of his arms by the village blacksmith and the strength and firmness of the muscles is appreciated by every one. On the other hand most of us know that if the smith were, unfortunately, to have his arm broken, necessitating it being kept bandaged up and in a sling for six weeks or two months, at the end of that period, the muscles would be mere ghosts of their former selves, and could no longer wield the hammer on the ringing anvil with the energy or regularity or precision that formerly won the admiration of the village youth. This is a mere instance of the general law that regular and appropriate exercise of a muscle, as indeed of any organ of the body, strengthens it and renders it more fit for the performance of its duties, while want of exercise or insufficent exercise is attended by gradual and increasing weakness, and if long enough persisted in, incapacity for duty.

The effects of Exercise upon the Heart and Circulation are well marked. The force of the heart's beat is increased and its frequency also. This effect is well known to all of us. When exercise is excessive it is usually the violence and speed of the heart's action or its irregularity that warn us we are overdoing our powers, and whenever we become aware of such unpleasant action we ought to accept it as a sufficient indication that the exercise should now cease. But the quickening of the heart and of the circulation caused by moderate and judicious effort ought only to be pleasant and exhilarating, and to this effect indeed is due much of the pleasure which appropriate exertion affords. The benefits of such quickening are shared by every organ of the body. The immediate result is, doubtless, to supply the active muscles with increased quantity of nutritive material, wherewith the increased chemical changes may be satisfied, but the indirect results are to stimulate the activity of other organs, lungs, liver, kidneys, skin, among the number, so that the whole body is awakened to more active life.

The effects of Exercise upon the Breathing are very important. There is an enormous difference between the amount of oxygen taken into the body during a period of rest and during a period of work, and also between the quantity of carbonic acid gas expelled during the same periods. Thus it has been found that a man at rest will absorb 417 grains of oxygen per hour, but during exercise 1829½, four and a half times the amount, and that during rest he will give out 603 grains of carbonic acid, but during exercise for a similar period 2501. Pettenkofer and Voit showed that during a day of work 2639 more grains of oxygen were absorbed and 4392 more grains of carbonic acid gas were given off than during a day of rest. At the same time there is increase in the quantity of watery vapour given off. This implies increased flow of blood through the lungs, more frequent expansion, and more complete expansion, of the lungs; it also implies greater activity of the muscles of the chest by which the movements of respiration are effected, and increased strength thereby. The value of such effects on the healthy condition of the lungs cannot be overrated. It has been strikingly shown that wind-instrument players, and those whose occupation implies regular and methodical expansion of the lungs, are singularly free from lung affections, and this can only be due to the bracing effect of the steady use of the organs. Whereas those who have little exercise seldom have the chest well expanded or the lungs well dilated, and the lessened vital changes implied must as surely weaken the lungs, as little exercise of the arm will be followed by weak and ineffective muscles.

The effects of Exercise on the Digestive Organs are always beneficial, if the exercise is well-timed; and there are no organs which more speedily indicate the evil effects of too little. Exercise taken too soon after a meal, whatever form it may assume, is injurious, because it diverts the blood stream from the stomach and associated organs to the muscles, and slows or arrests the natural process. But exercise, taken some time after food, aids the process in its later stages, and promotes the absorption of the nutritive portion of the food, by the quickening of the circulation, as well as by the effect of the increased movements of the diaphragm, due to the increased rate of breathing, and by other movements to which the intestine is subject. The activity of the liver is notably affected in a double way. It is stimulated by the frequent concussions that result from the bodily activity, and the increased consumption of the energy-

yielding foods, fats, sugars, and starches, removes from it materials which, but for the call upon them, would be stored up in the liver for future use. Sluggish liver is one of the most immediate results of deficient exercise. It is a familiar fact that constipation of the bowels is almost certain to arise when exercise is not engaged in, and, in consequence, all the abdominal organs become loaded, and a sense of languor, of easy fatigue, a tendency to headache, and a feeling of general indisposition to exertion speedily result.

Exercise also influences the Kidneys and Skin. This it does not only by the increased flow of blood through them, but also by the increased demand made upon them to remove the waste which the exercise has caused. The quantity of water removed by the skin during exercise may amount to several pounds weight. The effect of exercise will not only be to cause the removal of waste products, the result of exertion, but also the removal of waste which might otherwise have remained, useless material burdening the bodily organs, but for this stimulus to their removal.

Of the influence of Exercise on the Nervous System Dr. Crichton Browne speaks strongly and with the voice of authority. He argues from the fact that the stimulus to muscular contraction is conveyed by motor nerves, the stimulus, in the case of voluntary movement, originating in a certain region of the brain, called the motor area, whose business it is to preside over muscular movements, and from the fact that the muscular movement stimulates sensory nerves, which convey the impression made upon them to other centres in the brain. The exercise of the muscles means, consequently, the exercise of nerves, of nerve-centres also, of part of the brain itself. The training by which a child acquires the ability to perform certain movements with rapidity, regularity, energy, and precision, is a training not of muscles only but of nerve-centres also, of the nerve-centres set apart to reign over these special muscles. The actions which stimulate the growth and development of certain muscles stimulate also the growth and development of certain associated parts of the nervous system. Just as a muscle or group of muscles will show weakness and also wasting if the movements, for whose performance they are designed, are not practised, so also will the associated nerve-centres fail to develop or waste—atrophy—for want of exercise of their corresponding muscles. Children can with ease acquire dexterity in the performance of certain movements, as for instance those of the fingers in the playing of a musical instrument, which can only with difficulty be learned in mature life and then never thoroughly, chiefly because in the mature years the nerve-centres, whose business it would have been to preside over the movements, are no longer capable of full development, because of prolonged neglect. "For the hand-controlling centre, if not fully exercised at its nascent (growing) period, can never afterwards attain to the highest cunning; witness the clumsy caligraphy of those who learn to write in mature life, even when they practise with more than boyish assiduity, and the inferiority of the work of any craftsman who has not served a regular apprenticeship to his trade." "A large district of the brain is made up, as we have seen, of motor centres, and is concerned in motor ideas, which form a no less essential part of our mental stores than sensory ideas. The growth of that district of brain is evidently to some extent dependent on muscular exercise, and if that is withheld at the growth period the development of that district is arrested. And not only so, but that district is made up of a series of centres in relation with different groups of muscles, and each centre is dependent for its development upon the activity of its own group of muscles, and the defective exercise of any group of muscles during the growth period in its own particular centre will result in dwarfing of that centre and a corresponding hiatus, or a general weakness must exist in the whole mental fabric. From this we might deduce that swaddling-bands so applied at birth as to restrain all muscular movements, and kept up during infancy and childhood, would result in idiocy—a speculation to which the wretched muscular development of most idiots and imbeciles, and the fact that their mental training is most successfully begun and carried on through muscular lessons, give some countenance. We should also have to infer that, in order to build up a sound and vigorous brain, we must ensure free exercise to the different groups of muscles in the order of the development of their centres, and must in no degree interfere with the natural sequence of their evolution." Thus exercise, "besides being essential to the maintenance of nerve-centres in health, has very special relations to their development and growth," and so it may be made to contribute to brain growth, and to the symmetrical development of the mental faculties. "We thus see that an extensive region of the brain, in which the motor centres are situated, and which is of course in intimate

communication with all the other regions of the brain, can only be fully vigorous when the whole muscular system is fully vigorous also; and we recognize that good muscle work is essential to good brain work."

In the sentences that have been quoted, Sir J. Crichton Browne is speaking of the relation between the stimulus to growth of muscles and stimulus to growth of the nervous system in the period of youth, when growth is possible. But this does not imply that good muscular work is possible alongside of good brain work at the period of maturity. Rather the reverse is the case. Good brain work implies active and increased circulation of blood through the brain, even as good muscle work requires increased flow of blood to the active muscles. As the quantity of blood in the body is limited, the blood cannot supply the muscles in increased quantity and also the brain at the same time. Within certain limits exercise, implying quickened circulation, will stimulate the nervous system as well as the muscular, but the limits are narrow. Thus many a man, concentrating his thoughts on some subject, and finding his train of ideas somewhat slow of motion, forsakes his desk and paces up and down his room, finding in the stimulus of movement quickened thought. But in such mild exercise his brain gets a larger share of the increased flow of blood than his muscles. It is a different thing when a person really exerts himself, really causes his muscles to engage in active vigorous work, for then the determination of blood to the muscles diminishes the supply to the central nervous organs. Thus two men, walking along a road together, engaged in conversation, indicate by the speed of their movement the earnestness or profundity of their talk. If the conversation is really engrossing their thoughts, if their arguments are becoming closely reasoned, if they are keenly discussing a question with one another, the chances are that their movement is suggestive of aimlessness and uncertainty, halts are frequent, and more and more prolonged, till at the crisis of the discussion, both halt and stand face to face to argue the thing out. On the other hand, if the two are walking against time, with the desire of covering a certain amount of ground in a given time, it is the conversation that becomes halting and soon ceases, only an occasional word passing between the two. How common is it for men, who cannot get to sleep because the brain, pushed to its utmost activity by the demands of business or of professional work, will not quiet down or stop its turmoil of speculation, or calculation, or imagination, how common is it for men in such circumstances to get out of bed and pace the floor, or dress and go out for a steady walk of a mile or two, till the blood is brought down from the head to supply the active muscles, and the nerve-cells cease from troubling. Energetic muscular effort is opposed, that is to say, to vigorous mental work *carried on at the same time*, except that amount of brain effort that is necessarily associated with the muscular activity, the effort of will and so on. This is well proved by the mental state of those who give themselves up, more or less exclusively to muscular work, to athletic exercises, &c. The habitual use of the muscles to an excessive degree "tends to starve the brain" as Dr. Browne puts it, "or some portions of it by detaining large quantities of blood in the muscles to the detriment of the brain, and by limiting cerebral activity to certain tracts, and leaving other tracts wholly uncultivated. Professional athletes, and men entirely given up to sports of any kind implying great muscular effort, are generally dull and stupid; and a distressing hebetude creeps over boys who are permitted to neglect school work and concentrate their energies in gymnastics." At the same time, when there is no excessive devotion to the muscular effort to the neglect of the mental exercise, but when both organs get their due share of attention and their due call to activity, there is no manner of doubt of the benefits which the brain, in common with other organs of the body, derives from the muscular activity.

Moreover, it has been pointed out that systematic muscular exercise, by the effort of will which it implies, the training which accompanies it more or less, and the definite ends which are set up for effort and attainment, have an important bearing on character through their influence on the nervous system. "A consciousness of increased power is acquired, and this in turn begets self-confidence, resolution, and courage—qualities which, if rightly directed by proper moral and intellectual training, elevate the tone of the entire character, and aid to an important degree in subduing the passions. Indeed, the more perfect control which the mind possesses over a vigorous than over a morbidly sensitive body is a matter of everyday observation, and has given rise to Rousseau's seeming paradox "the weaker the body the more it commands; the stronger it is the more it obeys."

Exercise then is not a mere matter of muscle. It is not a mere question of firm energetic muscles against small flabby ones: it is a matter

affecting the whole being, body and mind. It is a question of the vigour of the whole man, concerning the general well-being of the whole body, not an activity suitable for boys and young men, but necessary for both sexes and at all ages, a potent, nay an absolutely indispensable agent in the growth and development of the child, and as necessary for the continued health and active life of the fully grown as are food and air.

Excessive and Defective Exercise.

Excessive Exercise.—The benefits which have been described as resulting from exercise are so great that one is apt to think one cannot have too much of it. This is, of course, a mistake. The occurrence of fatigue is the immediate effect and indication of over-exertion, though one only of temporary occurrence. It implies that waste has been occurring with greater rapidity than its repair admits of, and that is not a normal occurrence of healthy activity. The heart experiences, in healthy states, no fatigue, because its periods of rest and of activity are so rhythmically alternated, and in such due proportion, that the upbuilding of the wasted tissue and the removal of the products of waste keep pace with the process by which the waste is produced. It appears that fatigue is due mainly to the accumulation in the muscle of waste products, and is also a sensation due to exhaustion of the nerve-centres, from which the stimulation to muscular contraction proceeded. Other temporary effects of excessive exercise are muscular pains, tremblings, cramp, &c., which rest speedily removes, and whose removal may be much aided by gentle friction with the dry hand and by the hot bath. But other and more or less permanent effects may arise from excessive exercise, which it is necessary specially to note. Changes of a degenerative kind may arise in the muscles concerned, and this is specially the case when the exercise affects small muscles or small groups of muscles. Thus writer's cramp, pianist's cramp, are illustrations, and similar illustrations are afforded by telegraph operators, violinists, type-setters, and others. A most instructive form is that known as Hammer Palsy, to which pen-blade forgers are liable. The explanation, as given by Dr. F. Smith, who has studied this form of paralysis specially, is as follows:—"The pen-blade forger uses a hammer about three pounds in weight. A pen-blade receives, in the process of forging and joining to the piece of iron by which it is attached to the haft, on an average, one hundred blows. The forger, if an industrious man, anxious perhaps to save, by working overtime, enough money to join a building society or to commence business on his own account, will work twelve or thirteen hours in a day. He will make as many as twenty-four dozen blades in a day, and in so doing will deliver twenty-eight thousand eight hundred (28,800) accurate strokes. The rapidity and accuracy with which these blows rain upon the slender piece of iron are wonderful to the onlooker. Supposing him to work three hundred days in the year, and to continue this for ten years, he will in that period have delivered eighty-eight million four hundred thousand (88,400,000) strokes, and just so many discharges of nerve force will have occurred in the motor ganglia which are engaged in the action, and in the higher ganglia which calculate the distance and judge of the amount of force necessary to be used." The paralysis that ensues affects specially the right hand.

There are, however, injurious effects produced by excessive exercise not limited to small numbers of muscles. Excessive exercise, as indicated in the paragraph relating to the effects of exercise on the nervous system, develops the muscular system to the detriment of the central nervous system. Apart from this negative result, positive evils arise, specially affecting the heart, lungs, and blood-vessels. If there is habitually excess of muscular activity, the constant state of increased activity to which the heart is stimulated leads to an overgrowth of the muscular tissue of the organ—to hypertrophy; and this produces an uncomfortable sense of the heart's beat, which, as a rule, ought to occur without much consciousness of it. One has the feeling of the heart thumping against the ribs, a feeling of which one is most readily conscious when one retires to bed, and which sometimes hinders sleep, and a feeling apt to be excited whenever anything occurs to worry or harrass one. Such a feeling may be sometimes due to mere irritability of the heart without any actual overgrowth. Another effect apt to be produced is that of dilatation of the heart—the walls of the heart yield to the excessive pressure of blood within them, and once any yielding has occurred it is more likely to proceed. The dilatation may be accompanied by overgrowth of a compensatory kind, so that the heart becomes greatly enlarged. Such a result is most likely to arise when the exercise necessitates severe strains being suddenly thrown upon the heart. Thus if a person tries to lift a very heavy weight, he takes a very deep breath, then fixes the muscles of the abdomen and the diaphragm, and, holding his

breath, puts out all his strength. The pressure this produces upon the heart by the way in which the blood is detained in it is very great. Such a strain is always thrown on the heart in long diving, in lifting or hurling heavy weights, in taking long or high jumps and so on. The pressure thrown upon the lungs by the deep breath and the holding of it is also very likely to cause stretching of the walls of the air-cells, and ultimately a loss of elasticity of the lung tissue, so that the walls do not return to their usual state, and what is called emphysema (p. 283) occurs, just as an overblown india-rubber balloon will have a permanent bulge in some part of its wall. Besides these results, the blood-vessels may suffer by the excessive pressure of the blood within them. Rupture of a vessel or bleeding may occur, or a crack of the inner wall of one of the larger blood-vessels or a bulge of part of the wall may be the beginning of aneurism.

Excessive exercise of groups of large muscles is likely to end in the production of disproportion and deformity, as in the unequal shoulders of the horseman, because of the special development of the rein-holding limb, or the lob-sidedness of the schoolboy who always carries his books on one side.

It is to be noted that so far as these results occur in those fond of running, jumping, rowing, diving, &c., they are the consequences of bad regulation of the exercise, are very often doubtless the result of strain without previous training or preparation. The evil effects of sudden strain on lungs or heart, quite unused to it, are clearly revealed in the cases of men beyond middle life, after a quick run for a car or a hurry for a train. In them not infrequently the heart refuses the effort, and collapse is the result. The effects of too much exercise are usually seen in young men and men in the prime of life, who are fond of athletic sports, and are keen at competitions. It is in these cases that the desire to excel needs restraint and the firm guidance of some one experienced in training. In young children effects of excess are not seen. They follow their instincts and rest when fatigue threatens, not pushing their efforts beyond a safe limit. Boys and girls about the age of puberty (p. 472), however, need careful restraint.

Defective Exercise.—The evils of insufficient exercise are more numerous than those of excess. The youth who has never had sufficient exercise never attains to fulness of growth and development. He remains stunted, soft, and puny, wanting in vigorous circulation, and the ruddy glow of health. He is unfit for prolonged effort at work or play. Weak-chested as well as weak-limbed, nervous and awkward, he is defective in nervous as well as in muscular activity; and good mental as well as good muscular work is impossible to him. Imperfect general nutrition and bad digestion are his portion. Girls suffer most frequently from such conditions, because healthy natural movement is too commonly denied them. In them bad development of the figure, lateral curvature of the spine, popularly called "growing out of the shoulder" is a frequent result. In adults a falling-off of general health and vigour, an unhealthy deposit of fat, weakened heart and circulation, are results to be expected. The children of such parents inherit feeble constitutions, and one generation passes on the inheritance to another, producing a puny race unable to withstand the strain and pressure of life.

It is now time to consider briefly the various forms in which exercise can be taken and the advantages of each, as well as any special rules applicable to each kind.

Various Forms of Exercise.

Walking.—There is no form of muscular activity which brings into full play all the benefits to the body that exercise can confer like that of walking. It calls into play the greatest number of muscles, leaving none outside the range of its influence we may say, except those of the upper extremities. The action of the muscles appropriate to it is regular and methodical, not sudden nor spasmodic. It implies no undue strain upon any organ, supposing of course that it is not unduly prolonged; and it is suited to all ages, except, of course, the very youngest. At the outset the muscles of the trunk are concerned in the maintenance of the erect posture; and the swaying movements of the body, produced by the weight of the body being carried now by one leg now by the other, imply the harmonious co-operation of many muscles to prevent overbalancing. All the muscles of the lower limbs, those from the hip to the trunk, those which straighten the leg and those which bend it, the muscles moving the ankle-joint and those acting on the toes, all have their regular alternation of contraction and of relaxation, as the body is pushed forward, as the weight is gradually moved from the right leg to the left, as the body gets the final push from the right leg acting through the ball of the toes, as the right leg is raised and swung forwards, pendulum-like, while the left leg kept straight now

alone supports the weight, and so on. One group of muscles contracts after another in rhythmical fashion with each stage in the forward movement, while others imperceptibly and yet effectually maintain the balance. The muscles of the head and neck, of the chest and abdomen all have their share, great or small, in the ordered movement. Now this movement so apparently simple and easy is exceedingly complicated, and implies the expenditure of a very large amount of energy. The Rev. Professor Haughton, M.D., calculates that a man walking along a level road at a rate of about three miles an hour expends an amount of energy which would raise a weight equal to $\frac{1}{20}$ that of his body through a height equal to the distance walked. Thus a man who in his clothes weighs 150 lbs. walks, let us say, one mile. A mile is 1760 yards or 5280 feet. The $\frac{1}{20}$ of 150 is $7\frac{1}{2}$ lbs. He expends therefore energy equal to that needful to lift a weight of $7\frac{1}{2}$ lbs. 5250 feet into the air, or 1 foot 39,375 feet, that is 39,375 foot-pounds, or $17\frac{1}{2}$ foot-tons in round numbers (17·67 exactly).

Thus a man 150 lbs.	in weight	walking	1 mile	expends energy	which would	lift	$17\frac{7}{10}$	tons one	foot high.
,,	,,	,,	2 miles	,,	,,	,,	$35\frac{1}{3}$	,,	,,
,,	,,	,,	5 ,,	,,	,,	,,	88	,,	,,
,,	,,	,,	10 ,,	,,	,,	,,	$176\frac{7}{10}$	,,	,,
,,	,,	,,	20 ,,	,,	,,	,,	$353\frac{4}{10}$	,,	,,

If the man carries a weight—a parcel, an umbrella, a bag—this ought to be taken into account. If he carries an overcoat, whether over his arm or on his back, it ought also to be counted. If his overcoat weighs 5 lbs. this extra weight means the expenditure during every mile of a quantity of energy sufficient to raise nearly $\frac{3}{5}$ths of a ton 1 foot, and in the 20-mile walk amounts to nearly 12 foot-tons. But this is the calculation only for a level road. If at the end of his mile he has ascended 50 feet, this would need to be added to the number of foot-pounds in calculating the energy. He has raised his body (150 lbs.) this height, however gradual the ascent may have been, and 7500 foot-pounds or $3\frac{1}{3}$ foot-tons would need to be added. Now, according to Dr. Parkes, 300 foot-tons is an average day's work for a strong healthy adult. We can, therefore, calculate what number of miles walked along a level road will be equal to a good day's work. A 20-mile daily walk would, therefore, be above the average. According to Parkes "an amount of work equal to 500 tons lifted a foot is an extremely hard day's work, which perhaps few men could continue to do. Four hundred tons lifted a foot is a hard day's work. Now, according to the table 353·4 foot-tons is the work done in a 20-mile walk, so that 300 foot-tons would be almost exactly 17 miles. This walk is then a fair day's work on a level road. There are conspicuous illustrations of this amount of work in walking being enormously overdone, but for only limited periods. Thus the amount of work done by Weston in his six-days' walking match has been calculated. On the first day no less than 1525·3 foot-tons were performed, that is, energy was expended in walking sufficient to raise 1525·3 tons one foot high; and on the sixth day the work done equalled $967\frac{1}{2}$ foot-tons. The total amount of work done in the six days was equal to 7026 foot-tons, making a daily average of 1171 foot-tons. De Chaumont mentions an illustration of a European weighing 160 lbs. walking 73 miles, which would equal 1378 foot-tons, but it was done in about 17 hours, and thus became really equal to about 2400 foot-tons. For the speed with which the work is done affects the result, or, as de Chaumont puts it, "there is a velocity at which the maximum amount of work can be done at the minimum of expenditure." This, I believe, is also true in the case of a steam-engine. A steam-vessel may be built with engines fitted to take her at a moderate rate of speed, say 11 or 12 miles an hour, at a certain cost, but if she is wanted to go much faster, say 20 miles an hour, the cost increases out of all proportion to the increase of speed, so that in the steam-engine there is also a velocity at which a maximum of work can be done at a minimum of cost. In walking the economical rate is three miles an hour. This is the rate into which one naturally drops, when adopting a comfortable easy gait, and it is the ordinary rate of the soldier's march.

These calculations have been made on the assumption that the work is done under favourable circumstances, that there is, for example, absence of all restraint from the muscles, so that they have full freedom to go through their movements in a way natural to them. This implies appropriate dress. If owing to the wearing of a long overcoat, for example, the natural movements of the legs have been restrained, the same distance covered in the same time would imply the expenditure of a large amount of more energy.

Any restriction of the breathing is specially

disadvantageous in walking. The increased need of oxygen, which the continually increased expenditure of energy implies, means quickened breathing, and any garment so made, or so tightly worn, that free play to the chest is not permitted, will seriously inconvenience the walker. All these disadvantages are seen to the full in women's dress as a rule, the long skirts, the tight corsets preventing free movement of the lower ribs, and the close neckerchiefs, all being opposed to the free play of muscles that is desirable. In men tightly-buttoned close-fitting coats and high collars are also undesirable. Then, further, if each individual is to be permitted to expend his energy in a manner most economical his walk must be one suited to himself; the length of his step must be fitted to his length of limb; and his attitude must be the one which is least irksome to him, and which restrains him least. Thus a tall man and a short man, walking together at the same speed over the same ground and keeping step, do not spend the same energy in the walk. We shall suppose that the tall man is thinner than the short one, and that in spite of their different heights the two are the same weight. If the short man tries to suit his step to the tall man's he expends a great deal more energy than is needful, and if the tall man restrains his movements to suit his companion he also is not economical of energy. The two should walk along each suiting himself, so that the tall man's steps will likely be longer but fewer than his companion's. This illustrates one of the difficulties of the soldier's march, in which all have to keep together. The restraint implied not only by this necessity, but by the stiff attitude, &c., leads to the march being slower, and makes the impossibility of covering more than 10 to 15 miles per day, unless for a brief period and with the troops lightly equipped.

If, again, owing to the form of the boots, the natural elasticity of the step were destroyed, the work would be more laboriously performed, or if owing to projecting toes, the foot has to be raised to a greater height, at each step, to keep it from scraping the ground. If the heel of the boot is too high or too low, an unnecessary strain is thrown upon the muscles, in the first case to keep the body from being overbalanced forwards, and in the second case the calf muscles are unduly taxed in lifting the heel and throwing the weight of the body forward from one leg to the other. A double-soled boot should have a heel an inch deep, and a single-soled boot a heel just over ½ inch deep. The boots should be wide-soled, the soles projecting beyond the "uppers," when the weight of the body is borne by them.

Then, as has been indicated, ascending a hill implies a great increase in the expenditure of energy, for one must consider that the total weight of the body is raised. How great the expenditure may be for an apparently little height is shown by the following table, which indicates the expenditure of energy by a person weighing 150 pounds mounting a stair, every step of which is 6 inches high:

A person 150 lbs.	in mounting	1 step	expends	energy equal to	75	foot-pounds.
,,	,,	,,	5 steps	,,	,,	375	,,
,,	,,	,,	6 ,,	,,	,,	450	,,
,,	,,	,,	10 ,,	,,	,,	750	,,
,,	,,	,,	12 ,,	,,	,,	900	,,
,,	,,	,,	20 ,,	,,	,,	1500	,,
,,	,,	,,	30 ,,	,,	,,	2250	,,

This last is equal to a little over 1 foot-ton (=2240 foot-pounds), and is equal to the body raised only 15 feet. Supposing this stair to be ascended 10 times a-day, the energy expended, merely in the ascent, would thus be equal to raise over 10 tons 1 foot high, and if the stair were ascended 17 times the energy expended would have been sufficient for a walk of one mile. The number of steps this implies is only 510 of 6 inches each. But there are 2100 walking steps in a mile, assuming each step to be the regulation military step, namely 30 inches, so that each step, in ascending a stair where the steps are 6 inches high, requires the expenditure of as much energy as $4\frac{1}{10}$ steps of the regulation length on a level road. That is to say it requires the same amount of energy to lift one's body 6 inches high in the air as to carry one's body 123 inches along a level road by walking, that is $10\frac{1}{3}$ feet. That is to say the expenditure of energy that will raise the body a direct height of 12 inches, that is 1 foot, will carry the body by walking $20\frac{1}{2}$ feet, or, in other words, a climb of 1 mile means the expenditure of as much energy as a 20-mile walk on a level road.

It is, therefore, plain how persons able to walk only short distances, slowly and with great effort, become at once aware of the slightest rise in the ground. The sudden need of a much greater expenditure of energy tells at once on

the heart and the breathing, and the person is quickly brought to a standstill.

The various considerations that have been stated enable one to form a rough estimate of the daily amount of walking exercise each one should engage in. Take the case of the business man, who takes the omnibus or car to his place of business, spends the most of his day at his desk and returns home in the evening, little disposed to move out again in the evening. In the case of the young man, his pallor, bad digestion, headaches, and general languor and feebleness may be the results of the little exercise, in the case of the middle-aged man, perhaps it is increasing stoutness, breathlessness, rheumatic or gouty tendencies that warn of the need of muscle work and fresh air. Both are ordered more exercise, but of what kind and how much, both are commonly left in doubt. On this point Dr. Parkes says, "we can perhaps say, as an approximation, that every healthy man ought, if possible, to take a daily amount of exercise in some way, which shall not be less than 150 tons lifted 1 foot. This amount is equivalent to a walk of about nine miles; but then, as there is much exertion taken in the ordinary business of life, this amount may be in many cases reduced. It is not possible to lay down rules to meet all cases; but probably every man with the above facts before him could fix the amount necessary for himself with tolerable accuracy."

As regards women a daily expenditure of energy to the amount stated could not be borne by them. That the habit of daily exercise is one of which they stand in most urgent need is not gainsaid by anyone. A man's business, as a rule, takes him out of door, and if the risk of his taking too little exercise for health is great, how much greater is it in the case of women, whose duties as a rule keep them indoors? Thus it is that for days together many of them are not outside at all; then they sally forth on a shopping expedition, spend many hours lingering about shop windows and hanging over shop counters, and then return home fatigued to the uttermost, requiring several more days at home before a further expedition is ventured on. This is a most injurious system, not only because of the many days without out-of-door exercise, but also because of the sudden exertion put forth for which the body is unfitted. Of course in attending to their household duties, they have exercise, but exercise wanting the freshening and invigorating influence of exercise in the open air. It is because of the warmer air of the house, and because of its deficiency in oxygen, that this kind of exercise is uniformly tiring and never invigorating. A daily walk, amounting altogether to four miles, ought to be insisted on, and would materially conduce to the health and comfort and liveliness of the women of the household.

Concerning children not much need be said. If they are left to their healthy instincts no artificial standards need be applied, or artificial methods used. For them no exercise can take the place of the play in which they naturally indulge, by which one may say every muscle and every sense are exercised in due amount. No school system of exercise can take the place of the exercise which they will themselves take, if they are allowed freedom of healthy activity. The decorous walk cannot meet their natural instincts. It is a false system of education which ignores this fact, and which seeks to force young children to repress their natural tendencies to romp by imposing a standard of manners and a sedateness of behaviour suitable enough, may be, for their elders, making up for it by some gymnastic device or "calisthenic exercises." For children let particular care be taken that their dress is not inconsistent with their natural freedom of movement. Too often a desire to have their children dressed according to the current fashion makes parents "impose a style of dress which forbids healthful activity. To please the eye, colours and fabrics are chosen totally unfit to bear that rough usage which unrestrained play involves; and then to prevent damage the unrestrained play is interdicted. 'Get up this moment; you will soil your clean frock,' is the mandate issued to some urchin creeping about on the floor. 'Come back; you will dirty your stockings,' calls out the governess to one of her charges, who has left the foot-path to scramble up a bank. Thus is the evil doubled. That they may come up to their mamma's standard of prettiness, and be admired by her visitors, children must have habiliments deficient in quantity and unfit in texture; and that these easily-damaged habiliments may be kept clean and uninjured, the restless activity so natural and needful for the young is restrained. The exercise which becomes doubly requisite when the clothing is insufficient, is cut short, lest it should deface the clothing. Would that the terrible cruelty of this system could be seen by those who maintain it! We do not hesitate to say that, through enfeebled health, defective energies, and consequent non-success in life, thousands are an-

nually doomed to unhappiness by this unscrupulous regard for appearances; even when they are not by early death literally sacrificed to the Moloch of maternal vanity."

I have quoted these remarks of Herbert Spencer regarding the exercise that ought to be freely permitted to the young of both sexes, and I cannot do better than also transcribe what he has said regarding the physical education of girls. "To the importance of bodily exercise," he says, "most people are in some degree awake . . . at any rate, in so far as boys are concerned. . . . Unfortunately the fact is quite otherwise with girls. . . . Why this astonishing difference? Is it that the constitution of a girl differs so entirely from that of a boy as not to need these active exercises? Is it that a girl has none of the promptings to vociferous play by which boys are impelled? Or is it that, while in boys these promptings are to be regarded as stimuli to a bodily activity without which there cannot be adequate development, to their sisters, nature has given them for no purpose whatever—unless it be for the vexation of schoolmistresses. Perhaps, however, we mistake the aim of those who train the gentler sex. We have a vague suspicion that to produce a robust physique is thought undesirable; that rude health and abundant vigour are considered somewhat plebeian; that a certain delicacy, a strength not competent to more than a mile or two's walk, an appetite fastidious and easily satisfied, joined with that timidity which commonly accompanies feebleness, are held more ladylike. We do not expect that any would distinctly avow this; but we fancy the governess-mind is haunted by an ideal young lady bearing not a little resemblance to this type. If so, it must be admitted that the established system is admirably calculated to realize this ideal. But to suppose that such is the ideal of the opposite sex is a profound mistake. That men are not commonly drawn towards masculine women, is doubtless true. That such relative weakness as asks the protection of superior strength is an element of attraction, we quite admit. But the difference thus responded to by the feelings of men, is the natural, pre-established difference, which will assert itself without artificial appliances. And when, by artificial appliances, the degree of this difference is increased, it becomes an element of repulsion, rather than of attraction.

"'Then girls should be allowed to run wild—to become as rude as boys, and grow up into romps and hoydens!' exclaims some defender of the proprieties. This, we presume, is the ever-present dread of schoolmistresses. It appears, on inquiry, that at 'Establishments for Young Ladies' noisy play like that daily indulged in by boys is a punishable offence; and we infer that it is forbidden lest unladylike habits should be formed. The fear is quite groundless, however. For if the sportive activity allowed to boys does not prevent them growing up into gentlemen; why should a like sportive activity prevent girls from growing up into ladies? Rough as may have been their playground frolics, youths who have left school do not indulge in leap-frog in the street, or marbles in the drawing-room. Abandoning their jackets, they abandon at the same time boyish games; and display an anxiety—often a ludicrous anxiety—to avoid whatever is not manly. If now, on arriving at the due age, this feeling of masculine dignity puts so efficient a restraint on the sports of boyhood, will not the feeling of feminine modesty, gradually strengthening as maturity is approached, put an efficient restraint on the like sports of girlhood? Have not women even a greater regard for appearances than men? and will there not consequently arise in them even a stronger check to whatever is rough or boisterous? How absurd is the supposition that the womanly instincts would not assert themselves but for the rigorous discipline of schoolmistresses!

"In this, as in other cases, to remedy the evils of one artificiality, another artificiality has been introduced. The natural, spontaneous exercise having been forbidden, and the bad consequences of no exercise having become conspicuous, there has been adopted a system of factitious exercise—gymnastics. That this is better than nothing we admit; but that it is an adequate substitute for play we deny. The defects are both positive and negative. In the first place, these formal muscular motions, necessarily less varied than those accompanying juvenile sports, do not secure so equable a distribution of action to all parts of the body; whence it results that the exertion, falling on special parts, produces fatigue sooner than it would else have done: to which, in passing, let us add, that, if constantly repeated, this exertion of special parts leads to a disproportionate development. Again the quantity of exercise thus taken will be deficient, not only in consequence of uneven distribution, but there will be a further deficiency in consequence of lack of interest. Even when not made repulsive, as they sometimes are, by assuming the shape of appointed lessons, these monoto-

nous movements are sure to become wearisome from the absence of amusement. Competition, it is true, serves as a stimulus; but it is not a lasting stimulus, like that enjoyment which accompanies varied play. The weightiest objection, however, still remains. Besides being inferior in respect of the *quantity* of muscular exertion which they secure, gymnastics are still more inferior in respect of the *quality*. This comparative want of enjoyment which we have named as a cause of early desistance from artificial exercises, is also a cause of inferiority in the effects they produce on the system. The common assumption that, so long as the amount of bodily action is the same, it matters not whether it be pleasurable or otherwise, is a grave mistake. An agreeable mental excitement has a highly invigorating influence. . . . Granting then, as we do, that formal exercises of the limbs are better than nothing—granting, further, that they may be used with advantage as supplementary aids, we yet contend that they can never serve in place of the exercises prompted by nature. For girls, as well as boys, the sportive activities, to which the instincts impel, are essential to bodily welfare. Whoever forbids them, forbids the divinely-appointed means to physical development."

Running is a form of exercise indulged in without harm by healthy children of both sexes, and useful for growth of muscles, expansion of the lungs, and stimulation to the heart. It is not, however, desirable at the period of most rapid growth, when boys are passing into manhood and girls into womanhood. When this period is passed in boys, is the time for training for running, namely between the years of twenty and thirty. After thirty running, especially in races, is not advised. The rate of expenditure of energy is in running enormously increased. The length of step is usually not much increased; it is the rapidity of the step that is affected. Thus in soldiers the number of steps per minute at "quick march" is 116, and at "the double" 166, the length of step being increased only from 30 to 33 inches, so that the distance covered rises from 187 feet per minute to 453, the latter being equal to a little over a mile in 11 minutes. It is this fact that makes the short man excel in short races, and the tall man in long-distance races. For the latter can increase his steps to a greater number per minute more easily, provided his utmost speed does not need to be very long maintained, while the tall man's most convenient pace will enable him to cover a longer distance at a good speed.

Training suited for such exercise is given, as follows, by Maclaren in his book on training: "With a man unaccustomed to running, I would say, let him begin with a mile; setting himself to cover the distance in about eight or nine minutes, at the easiest pace and make-believe race he can run in. Let him break from his walk to the ground into an easy trot, and practise it until he find his wind decidedly improved, and the work, such as it is, pleasurable. He may then do one of two things—either increase the distance by another half-mile, to be run at the same pace, or hold to the same course and cover the distance in one or two minutes less. When the mile can be run in six minutes as easily as it was run in eight, let the tactics be changed; let him break the uniformity of the run, and cultivate variety of pace; let him begin the race, as at first, at an easy trot; keep at it for a quarter of the distance to allow the organs of respiration and circulation to take up gradually the accelerated action which is demanded of them as soon as the trotting begins, allowing the muscles employed in locomotion to take up their accelerated action when the walking is relinquished; let the second quarter be in the same style, but at a somewhat quickened pace, still keeping within the margin of easy performance; and let the third, if the preceding causes no distress, be quicker still, gradually culminating towards its close to an effort at the utmost strain of the powers; and last, let it subside in the fourth quarter gradually into the first easy trot, ending in the effortless walk, to allow the throb of the heart and swell of the arteries and veins to subside and settle down, and the lungs to resume their peaceful tidal motion, and the air current in their cells its rhythmical ebb and flow. I do not give these as absolute, but as approximate distances and rates of speed; they must be in all cases proportioned to the powers of the individual; but whatever may be his powers, let him begin within them, and augment the work, very gradually, whether in velocity or distance; and this augmentation should always be regulated by the actual advancement made by the running powers, until at speed and without preliminary breath or preparation the distance prescribed can be run. The distressing and often incapacitating pain of shin-ache is owing entirely to a disregard of this principle of gradual preparation. It is but the same kind of discomfort, arising from the same cause, which men out of practice feel in the arms on rowing suddenly at speed; that is, unpreparedness in the parts to

perform the work suddenly put upon them." Diet suited for such training has already been indicated on p. 621.

Jumping implies a sudden great expenditure of energy. Thus it is calculated that a jump 2 feet high, made by a man weighing 154 lbs., is equal to an expenditure of energy which would raise 308 lbs. 1 foot high, and the highest jump on record 6 feet 2½ inches "is equivalent to the sudden raising of 956 lbs., or about ⅜ths of a ton, and hurling it into the air." The strain of such an effort falls on few muscles—those of the calf of the leg and front of the thigh. The great effort is sometimes not unattended by harm to the muscles involved or the bones to which they are attached. The muscles are sometimes torn across, and the bones may be snapped by the strong and sudden contraction of the muscles. The bones thus affected are usually the small bone of the foreleg—the fibula—and the patella or knee-pan, the latter of which is broken across by the pull of the straight muscle of the thigh—the rectus (see p. 74). Rupture may also be produced. Jumping of any extensive kind should not be engaged in without previous training, such as that for running, and the best age is said to be between the nineteenth and twenty-fifth years.

Riding is, next to walking, the most universally useful form of exercise. Pleasant to youth, it also has so much attraction for the elderly, that they enjoy the daily horse exercise when they could not be induced to walk. It is capable of so much modification, as regards the actual amount of effort put forth, that it may be suited to many for whom very active exercise is not desired. Thus though the horse may go at little more than a walking pace, and the rider may put forth practically no effort at all, yet he may be carried a considerable distance, so as to obtain to the full the exhilarating influence of fresh air without fatigue. Then even at such an easy gait, and with little exertion, the movements of the horse communicated to the rider produce very considerable stimulating effects upon the liver and other abdominal organs. It is, on this account, an invaluable form of exercise for men beyond the mid term of life, who lead sedentary lives, and who either will not or cannot put forth the energy, which a walk sufficient for purposes of health would imply. In the gentle canter they get the needed stimulus to the digestive organs without fatigue. It is this property of stimulating the abdominal organs by the rhythmical shocks, produced by the movement of riding, that makes exercise on horseback so peculiarly the kind of exercise for the dyspeptic. While thus capable of being made one of the gentlest kinds of exercise, it of course affords scope for much more vigorous effort. For women it is a very suitable kind of exercise, provided due discrimination be employed. Wherever the means of parents permit of it, children should be taught riding, although the daily riding lesson or canter ought never to be substituted for play or deemed sufficient exercise. Constant riding produces characteristic changes in certain parts of the body. Wasting of the muscles of the inner side of the thigh results from the continual over-exertion of these muscles in keeping the knees pressed against the horses' sides; and to this the awkward walking gait of ostlers is due. Then the marked disproportion in the use of the left hand and arm over the right, by holding the reins, occasions a prominence of the left shoulder particularly likely to be marked in girls and women. The remedy for these defects is to avoid making riding an exclusive form of exercise, and if children are allowed full scope for play and other forms of recreation, such as tennis, &c., they are not so likely to arise. It may be remarked that it is of very great importance to anyone who is to have frequent occasion to be on horseback that he should be suited to a horse. A short-limbed man on a broad-backed horse must suffer some distortion of the limbs, and if he is subject frequently to the improper position, it will undoubtedly leave its evidence permanently on the shape of his limbs. The reverse conditions would tend to make a man knock-kneed. "The men who show least deformity are those of a medium height, of about 5 feet 8 inches." The need of remembering this fact in the case of growing children, with their soft yielding bones, is apparent.

Rowing is, according to Maclaren, the chief of all our recreative exercises; no other can enter the lists against it. There is a difference, however, according to the same authority, between rowing as an exercise and rowing as an art for the object of sending a boat at the greatest speed through the water. In the latter case the boats are so constructed, they are so light, they offer so little resistance to the water, the "form" of stroke adopted is such, that "a boat-race has now become a matter of wind rather than of muscle," and, as an old waterman remarked to Maclaren at a university race, "The crew that can bucket it the fastest will win the race, *if they don't bu'st.*" Owing to the diminished resistance of the boat, way is not kept up

unless by short quick strokes, implying great strain upon the heart and lungs rather than great muscular exertion, so that it has become a question of "wind" rather than of muscle. On this account modern alterations in the directions noted "have advanced rowing as an art, but detracted from it as an exercise." Regarding rowing as thus practised, Maclaren says, it gives "employment to a large portion of the back, more to the loins and hips, and most of all to the legs; but it gives little to the arms, and that chiefly to the forearm (because of the actions of grasping and feathering the oar), and least of all to the chest. Moreover, as there is but *one* movement in rowing, namely, the stroke, indefinitely repeated with the most rigid precision, and as it is in the rearward half of this movement only that any real muscular effort is made or resistance encountered, it follows that every muscle of the body not employed in this action is excluded from the exercise; moreover, also, every muscle included in it is employed in but one line of action, while it is qualified and designed to act in many, and will be developed and strengthened in proportion as these manifold modes of its use are observed; and moreover, again, as, with few exceptions, all muscles have antagonistic muscles, designed to perform counter movements, it follows that as rowing consists of but one motion, the antagonistic muscles of those employed in executing this motion must be virtually unemployed. Thus, as I have said, the legs have strong employment in rowing, but it is the *extensor* muscles alone which have actual employment; the *flexors* are comparatively idle; they perform no exercise, they gain no bulk, they obtain no increase in power. They are excluded from the work, they have no share in the reward. . . . The part of the body which receives the smallest share of the exercise in rowing is the chest; it has little or no employment in the muscular effort required for the propulsion of the boat; and this is impressively evident in the results. Not only does it make no advance in development in this exercise, but, if it be exclusively practised, an absolutely depressing effect is exercised." Maclaren goes on to say that this result of falling off in growth of certain parts of the body by exclusive devotion to one exercise is common to any single exercise, and that some complementary exercise is required for developing these parts so neglected. For rowing he thinks the added exercise should be one which, while giving work to the muscles not employed in rowing, will in particular develop the respiratory capacity, for in rowing "respiratory power makes the first claim, and makes it more exactingly than in any other mode of physical exertion in which men can be engaged, not only on account of the rapidity of the inspirations and expirations, and not only from the fact that they are *not* regulated by the natural action of the lungs themselves, but by the artificial movements of the exercise, but also from the interruptions caused by the fixing of the chest, and forcibly holding in the lungs of the air inspired after, in the natural order of the function, it would have been expelled." The best auxiliary exercise in the case of rowing he thinks is running, when engaged in in a regular methodical way, as indicated on p. 754.

In ordinary rowing, however, rowing for pleasure, the pastime so almost universally engaged in during summer holidays on river or lake or at the sea-coast, the circumstances are very different. The build of the boats is different, and in every way there is much more resistance to be overcome, and, therefore, much more muscular effort put forth. Moreover the effort is put forth in a different manner, for the long swing of the back is very different both in its effects upon the muscles, and in its effects upon the heart and lungs, from the quick high-pressure stroke of the racer. The steady swinging stroke of moderate length, kept up, say by four persons, in a four-oared boat, which carries other persons as well as provisions, let us suppose, for the party going for a picnic by water, implies chiefly muscular effort, and no special strain upon the respiratory organs. In such rowing many groups of muscles receive exercise. No muscles are more exercised than those of the back, and those passing between the trunk and the lower limbs, both in the backward swing and the forward movement. For keeping up such exercise for any length of time, it is necessary that the breathing be accelerated little above the ordinary rate. A stroke of 20 to 25 can be well maintained, and will give good speed.

It is, then, really the latter circumstances that one must consider most, and for which one may state a few of the accepted rules. First of all, the clothing should be loose, tight nowhere. Women should specially note this condition. Stays ought, for such exercise at least, be laid aside. With them neither the muscles of the back get full play, nor does the breathing. For girls whose back muscles have had little opportunity of development, no exercise could be more recommended, provided it

be engaged in in a judicious way and not rushed at. The clothing should be of flannel material, and should be changed when the exercise is over. An extra coat or wrap of some kind should be at hand in the boat, to be put on if one stops rowing for a little. The breathing should not be restricted during the stroke; the breath should not be held, for that would imply holding the breath for a considerable time, then letting it go and taking in a new breath in a much shorter time than is usual. This implies a complete alteration in the natural rhythm of respiration, which leads to breathlessness and speedy fatigue. Indeed the quick onset of fatigue in the inexperienced rower is commonly, not the result of muscular effort, but the consequence of interference with breathing, and a deficiency of oxygen in the tissues. Let the breathing, then, be as natural as possible as to rhythm; accelerated slightly it will naturally be. Then the exercise is not to be engaged in without some regard for muscles unaccustomed to that form of activity. The youth whose only opportunity of such pastime is during the summer holiday, ought not to go at it his first day, as if he had been engaged in no other occupation all his life. Some restraint must be exercised; a little the first day at a quiet easy pace will prepare for a little more the second, and still more the third, till after several days more prolonged and vigorous effort may be indulged in with ease. The rower should stop whenever fatigue threatens; and he should never engage in the exertion till an hour or more after a full meal. Blisters are to be prevented by the handle of the oar being quite smooth, and being kept quite dry, by the hand being dry, sweat being removed (and to the same end dusting with white oxide of zinc powder is advised), and by never allowing the oar to slide in the hand, all "feathering" being executed from the wrist and elbow, chiefly from the wrist. If blisters threaten, "stop rowing for an hour, wash the hands well with soap and water, wipe the tender parts over with some vinegar, and then gently rub spirits of wine, or, if that is not available, whisky, gin, or brandy over the tender parts, drying the parts perfectly between each step of the process."

Lawn Tennis is one of the best of modern exercises, combining, as it does, an infinite variety of muscular effort, with a high degree of pleasurable excitement, and demanding and cultivating mental as well as physical alertness. It does not give mere exercise to the muscles, but it affords also a training in the art of constantly varying the quantity of energy expended to suit a particular purpose. It involves also some education in judging of distances, and the eyes receive no small part of the educational effect. One may say that it puts every muscle of the body into active exercise. Take the arm as an example; the muscles which bend as well as those which straighten it, the muscles which carry it away from the body, and those which carry it across the body, those which carry it high into the air, those which swing it backward and those which carry it forwards, are all in rapid succession called on for full activity. At one instant the forearm is rapidly twisted to deliver a backhanded blow, and at the next the action is as quickly reversed to take the return ball off the other side. Similarly every other part of the body has its work to do, as the player bends well forward to catch a low ball, now throws his body to one side now to the other, now bending well back, or jumping high in the air to stop a high ball, all the while his legs have to be on the alert to carry him wherever the vagaries of the game may demand his presence. It is a game in which anyone may take part, from the 8-year-old to his grandfather, a suitable partner only being necessary. It is a game in which women may hold their own with men, and meet them on nearly equal terms. Perhaps there is no game which will so rapidly impress women with the evils of fashionable dress.

No game involving vigorous exercise is without some kind of risk, and lawn tennis is no exception to the rule. The extreme rapidity and suddenness with which movements must be effected in every game, in which the players are even moderately expert, tend to produce sprains of tendons and tears of muscle. In particular, a tear of tendon or muscle is common in the neighbourhood of the elbow-joint, causing what is now called **tennis elbow**. It is either a tear of ligament over the head of the radius, the outer of the forearm bones, due to rapid turning of the hand palm-downwards, to deliver a backhanded stroke, or it is a tear of one of the muscles, by whose contraction the arm is recovered from this position. In each case the pain is below the elbow-joint on the outer side of the fore-arm. The treatment is complete rest from the game for the remainder of the season. The part should be gently rubbed upwards, and an elastic elbow-cap may be worn. Other muscles are apt to suffer in a similar way. The biceps is sometimes torn near its point of origin, at the inner and upper part of the arm

(see Fig. 67, p. 72), at which place a swelling immediately appears, and the arm drops. Rupture of the tendo Achillis (p. 75) may also happen, though it is not common, consequent upon the taking of a sudden forcible spring. Rest and rubbing, rubbing of the massage type are the remedies.

Bicycling and Tricycling.—This is a form of exercise which has grown immensely in popular favour of recent years. At first sight the muscular effort involved in driving the bicycle might seem greater than that required for the tricycle, because with the former machine the action of a great many antagonistic muscles is involved in maintaining the balance, but in reality the work done in driving the latter is much greater. It is quite true that the beginner speedily experiences a sense of fatigue, not restricted to the lower limbs, but general to the whole body, due to the strain in attempting to keep his balance. This is, however, because he has not acquired the art of nicely adjusting the action of the various muscles for the desired result. It is a misuse of his muscular effort, just as the child learning to walk expends a great deal of effort uselessly. The person who has acquired the art of sitting his machine is hardly conscious of the action of the various muscles which maintain the balance. On the bicycle the weight of the rider is partly supported by the saddle, and is partly made most effective use of in driving by being borne in the treadles, supposing, that is, that the height of the wheel is properly suited to his length of limb. It is, therefore, the muscles of the legs that are specially exercised, and in particular the extensors, which straighten the leg, and drive down the treadles, the way on the machine carrying the wheels round and diminishing the work to be done in lifting the legs. The arms, of course, also do effective work in guiding, the muscular tension involved in keeping the levers in the proper position involving steady effort, though an expert rider can so balance himself as greatly to diminish the strain upon the arms. On a level road, for example, the experienced rider can go a considerable way without his hands on the handle at all, so nice are the muscular adjustments which maintain the balance, but whenever any difficulty on the road occurs the muscles of the arms are at once and actively engaged. After a ride of long duration, the fact that a large number of the muscles of the body have been unconsciously engaged in the work is evident from the feeling of general fatigue, not fatigue limited to the legs or ankles or arms, but affecting also the loins and back. Now, on the tricycle the necessity of a fine adjustment of the body is not so needful, and certainly not so urgent, because the machine maintains its own balance. If the height of the saddle is properly adjusted, the rider is almost in the erect position and bears with a large proportion of his weight upon the treadles, but if his seat is somewhat low he will speedily become aware of the position of the most active muscles from the feeling of intense strain and weariedness in the muscles of the front of the thigh, the muscles which straighten the legs and thus drive down the treadles. In this case his weight is mainly borne on the seat and is largely lost as a means of propulsion. In the case of the tricycle, however, the extra weight of the machine, the increased friction from the number of wheels, and the diminished diameter of the wheels, necessitate a greater expenditure of energy for the same distance covered. Dr. James Cantlie thus calculates the expenditure of energy in the driving of the bicycle: "Take, for example, a bicycle with a wheel of 60 inches diameter, every stroke with the foot causes the wheel to travel half its circumference, or nearly 7½ feet, that is 90 inches. This is equivalent to three regulation walking steps of 30 inches; and not only so, but the impetus given to the bicycle by one stroke would carry it much further, whereas a step in walking gives no further 'way' on the body. Hence each stroke becomes lighter after the first, and less and less exertion is required to keep the machine in motion. From all these reasons, then, and from actual observation of the effect of comparative distances travelled, it is plain that to travel a mile on a bicycle is equivalent in muscular expenditure to about one-sixth of that expended in walking a like distance. The exertion spent in travelling a mile on the 'level' on a bicycle is not more than four foot-tons, so that, as 300 foot-tons is the calculated amount of daily exertion (see p. 751) necessary to expend to keep a man in health, an 80-mile ride can be undertaken by a man without danger of overdoing it. No road, however, is level or smooth; hence it is nearer the truth when the exertion expended is considered to be six foot-tons a mile; limiting the distance which ought to be travelled to less than 60 miles a day, if one is to keep within the bounds in regard to the energy expended. Of course, a healthy man can do much more than 300 foot-tons a day, but an exertion greatly over that amount cannot be continued

day after day without injury to the health." He calculates that 40 miles a day is about the maximum distance that ought to be attained on a tricycle, and at a rate of not more than six miles an hour.

When one considers the distance that can, after a little practice, be covered easily in an hour or two by even the tricycle, one perceives the value it possesses as a means of exercise. In half an hour one can be rid of the town and out in the open country, getting with the exercise the fresh air, perhaps not otherwise attainable, without risk and, after the initial cost of the machine, without expense. It is a suitable exercise for women as for men, for the elderly as for the young.

There is, however, great temptation to put on speed and to cover startling distances in the minimum of time. Any one who has seen a young man dismount from his bicycle with every vein of his face and head standing out, and with his face turgid with exertion, and purple from deficient respiration, does not need to be told that in this exercise, as in others, the pace may kill. The concentration of effort in the legs, for the attainment of speed, almost necessarily involves a fixing of the chest, as well as the strain put upon the arms to maintain a straight course by pressure on the handles. This means insufficient breathing, want of aeration of the blood, breathlessness, and so on. Beginners are apt by the vigour of their grasp to produce this fixing of the chest and speedy breathlessness, even when trying to go at no more than a moderate speed.

The vibrations communicated to the body by stimulating the abdominal organs are useful in certain sluggish states of the bowels, &c., such as may be a cause of indigestion, constipation, &c. But the bicycle should not be mounted by any suffering from heart or lung affections or with a tendency to rupture. They should have medical advice before using even a tricycle. The writer is not sure that a bicycle, or tricycle even, is a useful means of exercise for anyone suffering from marked disorder of the liver. It ought to be useful, by the stimulus it occasions, to slight sluggishness of liver, *if the exercise is taken in moderation and at a gentle speed*, but he is convinced he has seen it do much harm, in the case of a youth who was very fond of the machine and indulged in long rides, and was fond of making good records.

The dress should be of light woollen material, and well-fitting without being tight, that is the usual amplitude of garments is undesirable; a waterproof coat should be carried, and the cap should be of woollen material. Specially should the neck be free of constriction, and the loins, the knees also. Stockings should be kept in position by some other method, rather than by the tightness of knickerbockers, or anything of the garter kind. Ladies should wear light flannel garments, of no unnecessary length; and the objection to constriction applies to common articles of their dress which have already been objected to at sufficient length in this work (p. 472).

Cricket and Football vary very much in the amount of exercise they give to the body, which depends on the part the individual player must take in the game. The individual must merge himself in the body of men with whom he is associated. The game of cricket supplies all that an exercise should, work for the whole body, needing quickness of eye and alertness of judgment as well as good muscular development. For boys at school it is the most excellent of games, provided a boy plays with others of his own size and years, who will consequently bowl and hit with a strength to which he is equal. Its chief evil is the waiting about necessary before one has his turn at the wickets, during which the cricketer is not too careful to don an extra garment. In the game of football more risks are run than in any other. It calls for sudden efforts, to be followed by periods of waiting of longer or shorter duration. In consequence the pressure on heart and lungs is often very great, and the risks of lung affections from cold by no means small, not to speak of the frequency of accidental injury.

For both games a little training, of the kind which strengthens the organs of circulation and respiration, should be undertaken before the season begins. The best for this purpose is the training for running, which is given in detail on p. 754.

Golf, a Scotch game to begin with, is now rapidly becoming popular all over the United Kingdom. It is the perfection of an outdoor game. It implies walking at a steady even pace without hurry or excitement, abundant exercise, though not excessive, to the arms, an education to the eye in estimating distances, and a training in graduating the amount of force to be used to send the ball the needful distance, and the niceties of the game afford an educational influence of great variety and high order. It is a game enjoyed by both sexes, and at all ages; and one may say there is no disease, which does not prevent one wielding a club, in which it would be improper.

GYMNASTIC EXERCISES.

Gymnastic exercises are too often regarded from too narrow a point of view. Many people think of a gymnasium as a place where youths are put through a course of exercises to enable them to accomplish some particular feat, or to acquire some particular kind of dexterity. It is a place where one learns to fence, to leap, to turn somersaults and so on. This is not a correct view, though it is one unfortunately encouraged by the bad system pursued in many gymnasia, where the pupils are set to practise certain limited movements, the aim being to achieve a certain result in the length or height of a jump and so on. The result of any training, the chief end and object of which are the accomplishment of some feat or several feats, is that certain muscles of the pupil's body are developed to a great degree, while others are developed to a much less degree or are neglected. The consequence is a disproportion of parts, a want of harmonious growth and development of the whole body. It is commonly the lower limbs that suffer in this way, the upper part of the body being developed out of proportion to them. Now there is nothing in the term gymnastic restricting the kind of exercise. It is derived from the Greek, *gymnos*, naked, simply because the Greek stripped to his exercise; and the word does not, therefore, indicate the kind of exercise, but simply that the athlete removed all possible clothing so that there should be no hindrance to the full exercise of his whole body. Now the only aim, which gymnastic exercises should have, is the methodical training of all the muscles of the body for the purpose of promoting the highest possible development of all the powers and activities of the body, consistent with health. The object is not the accomplishment of a feat, which can be paraded on exhibition, but the perfecting of the physical framework of the body. As we have already pointed out such perfecting of the physical framework of the body, when not unduly pursued, is not without marked influence on the mental and moral sides of the individual. Such exercises then ought to be considered as essential parts of a good all-round education. Education, that is to say, ought not to be restricted to the intellectual powers. It ought to include the training of the body, and as a result one would have more frequent illustration of the "sound mind in a sound body" than is yet common. Gymnastic exercises ought to include every kind of muscular movement that is fitted to promote a harmonious development of the healthy body as a whole. They ought not to be looked at as the appropriate exercises for the production of athletes, but the necessary training for the production of healthy men *and women.*

It is to Peter Henry Ling, who was born at Smaland, in Sweden, in 1766, that we are indebted for a scientific system of bodily exercises. Student of theology, tutor, naval volunteer, and teacher of modern languages in turn, Ling, in 1806, became fencing master at the university gymnasium at Lund, Sweden, where he began to put in practise his views of a rational method of gymnastic exercise. Finally he was made a professor at Stockholm and director of a central establishment, founded for the practice of his system of movements, a system which was subsequently introduced into all the military academies of Sweden, town schools, universities, colleges, and even into orphan institutions and country schools. In the central institution the movements were also applied for the treatment of disease. Ling's idea was that "an harmonious organic development of the body, and of its powers and capabilities by exercise, considered in relation to the organic and intellectual faculties, ought to constitute an essential part in the general education of a people." He based his system of gymnastics on anatomy and physiology, each movement being designed for the exercise of a particular muscle or group of muscles, and the whole set of movements thus affording effective and appropriate work to all the various muscles, without unnecessary exertion or fatigue on the part of any. The design of such a system implies, therefore, a knowledge of the actions proper to each muscle or group of muscles, and the movements by which each can be brought into activity.

Nowadays, chiefly owing to the teaching of Ling and his pupils, methodical and graduated muscular exercises are employed both for the development of the healthy body and for the treatment of disordered states, such, for example, as spinal curvatures. In lateral spinal curvature, indeed, graduated muscular exercises afford almost the only suitable kind of treatment. There are many books now to be had, well illustrated, in which a great variety of exercises suitable for children and youths are well described, the performance of which is well fitted to develop the body in a healthy way. We shall give here only such exercises as might be made use of in any home, which require little or no apparatus, and which at the same time will put into action most of the muscles of the body.

EXERCISES WITHOUT APPARATUS.

If several persons are about to engage in the exercises, let them stand in line about 6 feet apart; let the instructor stand a little in front opposite the centre of the line. When he gives the word of command he should himself, at least at first, go through the movements, so that the pupils are aided in understanding their exact character.

The **position** in which each pupil should stand is that of **attention**, as it is called in the army. It is thus described:—The exact squareness of the shoulders and body to the front is the first and great principle of the position. The heels must be in line and closed. The knees should be straight, the toes turned out so that the feet may form an angle of 45°, the arms hanging easily from the shoulder, the hand open, the thumb to the front and close to the forefinger. The fingers should lightly touch the thigh, the hips being rather drawn back, and breast advanced, but without constraint. The body should be straight and inclining forwards, so that the weight of it may bear principally on the fore-part of the feet. The head is to be erect, but not thrown back, the chin being slightly drawn in, and the eyes looking straight to the front. This position is given in Fig. 297.

Fig. 297.

Fig. 298.

Stand at Ease is the next position to be taught. The arms are raised from the elbows, the right one as high as the right breast, with the palm directed to the left and to the front, the left one as high as the waist, with its palm upwards. During the movement the thumbs are separated from the forefingers, and throughout it the elbows are kept steadily pressing against the sides. This is the first part of the movement. At the next part the pupil strikes the palm of the right hand on that of the left, the arms are dropped to their full extent, the hands keeping together, and as they fall the right hand slips over the back of the left. At the same time the right foot is drawn back 6 inches, so that its instep is placed against the left heel. The weight of the body is supported on the right leg, the left knee being slightly bent (Fig. 298). In this position the whole attitude should be without constraint, the arms should hang loosely and easily, the fingers pointing towards the ground, the right thumb being lightly held between the thumb and palm of the left hand.

When the teacher has shown to each pupil the correct positions, he should exercise them in taking it together. Standing in front he gives the word of command, dividing the command into two halves, thus, *Stand at—Ease*, pausing for an instant after the first half, so that the children, knowing what is to come are all ready to act together when the second half is called out, in a quick, sharp tone. The first half is called, the **caution**, and is the signal to be ready. The orders are thus:—

Atten—(pause) *tion; Stand at*—(pause) *Ease.*

Those orders should be given several times, one after the other, say six or eight times, till the pupils get accustomed to assume the positions quickly *and all together.*

The caution is made a little longer, so that a little more warning is given, by the instructor calling out *Boys* (or *Girls* as the case may be) before giving the order, *Attention,* just as in army drill the officer precedes his order by the word *squad, company,* &c., according as he is addressing a squad or company.

First Arm Exercise.

Let the pupils stand in position of attention, and let them then be put through the following movements:—1. The arms are quickly bent at the elbow joint, the elbow being held well back and close to the side; the fingers are slightly bent, their points touching the shoulders. 2. The arms are rapidly raised and fully stretched above the head, the palms *being turned inwards.* 3. The arms, fully stretched out and without the least yielding at the elbow, are brought rapidly down, till they extend straight outwards in line with the shoulders, palms *downwards.* 4. The position of attention, the

position from which the movements began, is resumed.

The instructor, standing in front of the line of pupils, would conduct this exercise as follows, and by the following commands:—

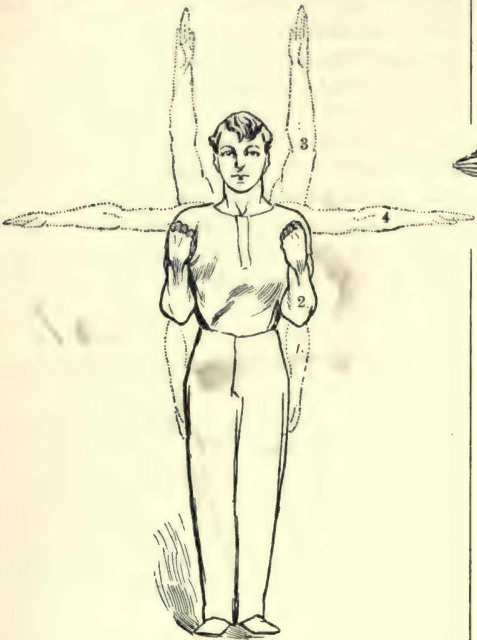

Fig. 299.

Boys (or *Girls*), *Atten—tion.*

For First Arm Exercise (this he calls out to let the pupils know what movements they are to execute).

Then, *One* (the pupils assume position 2 of Fig. 299).
Two (,, ,, ,, 3 ,, Fig. 299).
Three (,, ,, ,, 4 ,, Fig. 299).
Four (,, ,, ,, 1 ,, Fig. 299).

This exercise should be repeated eight times. End with the order *Stand at—Ease.* It may be varied by causing the pupils to perform it with one arm only. The instructor, in giving the caution *For First Arm Exercise,* would add—*with right* (or left) *arm only.*

Second Arm Exercise.

The pupils first get the command *atten—tion,* springing at once into the proper position. The movements they are now put through are as follows:—1. The arms are thrown straight up to their full height, as in 3 of Fig. 299. 2. The arms are stretched straight out in front, palms together, as in Fig. 300, the elbows being kept perfectly straight in executing the movement. 3. The arms are swung, fully stretched, to the back, and kept there, palms being struck together. This movement is a difficult one. The instructor must see that in this position the shoulders are straight, head well up, but chin drawn in, and eyes to the front (Fig. 301). 4. The arms are swung, fully extended, to the position of number 2, Fig. 300. 5. The first position, that of attention, is resumed.

Fig. 300.

Fig. 301.

The commands for this exercise are consequently as follows:—

Boys (or *Girls*), *Atten—tion.*

For Second Arm Exercise—

One (position shown as 3 of Fig. 299).
Two (,, ,, in Fig. 300).
Three (,, ,, ,, Fig. 301).
Four (,, ,, ,, Fig. 300).
Five (,, ,, ,, Fig. 297).

Repeat this exercise six times. End with the order—*Stand at—Ease.*

Third Arm Exercise.

From the position of attention the following movements are made:—1. The arms are swung, fully extended all the time, outwards and upwards till they are stretched, straight above the head, *palms to the front* (Fig. 302). 2. The arms are brought down, at the stretch, till they extend straight out in line from the shoulders, *palms upwards* (as in 4, Fig. 299, with the difference of the palms being upwards instead of downwards). 3. The upper arm being kept steady, the elbows are rapidly bent, and the fingers brought to touch the tips of the shoulders (Fig. 303). 4. The position of number 2 is resumed. 5. The arms are brought down to attention.

The commands for this exercise are:—

Boys (or *Girls*), *Atten—tion.*
For Third Arm Exercise—

One (see Fig. 302).
Two („ Fig. 299).
Three („ Fig. 303).
Four („ Fig. 299).
Five (the position of attention).

Repeat this exercise eight times. End with the order—*Stand at—Ease.*

Fig. 302.

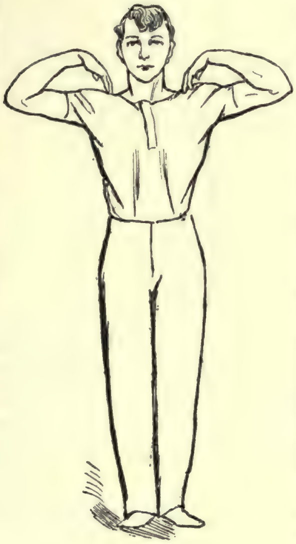

Fig. 303.

These exercises bring into activity the muscle which bends the forearm at the elbow—the biceps (see Fig. 67, p. 72), the muscle which straightens the arm—the triceps, the muscles which raise the arm, of which the deltoid and trapezius (p. 72) are the chief, the muscles of the back, which, acting from the spine, pull the arms backwards, the muscles which clothe the chest and carry the arms forwards, and the muscles which turn the hand into the prone and supine positions. But they do more: they act vigorously in expanding the chest. When the arms are strongly extended above the head, the ribs are raised, the cavity of the chest is enlarged and the lungs in consequence are more distended with air, and the vigorous pull on the shoulders by the backward movements of the arms has a similar effect.

While the pupils are being put through these exercises they must be cautioned against holding their breath. They ought to breathe freely and deeply all the time, never holding the breath at all. If the breath is held, and at first many will be found to do so, the pupil will be rapidly tired, simply from want of air. But if breathing is steadily and regularly maintained, fatigue will not quickly appear. Further the teacher must, at the beginning, be content with one exercise, repeated a few times. As progress is made several exercises may be gone through, one after the other.

When the pupils become accustomed to the movements, they must be caused to perform them with speed and energy. The arms must be extended, for example, with force, as if to hit something, and no matter how many children are in the line, the arms should shoot out, instantly at the word of command, as if from one body.

When the children have become acquainted with the exercises they may execute them to music, or, after they have been arranged in line and have assumed the "attention" position, they may, at a word from the instructor, proceed with them themselves without further command, the whole company acting together and chanting the numbers—*One—and two—and three—and four*—repeating the exercise over and over again till the instructor may call the halt. All this time the instructor simply watches the movements, seeing that all the children work together and keeping the whole line in order.

Head Exercise.

From the position of attention the following movements are made:—1. The hands are placed on the hips, fingers being in front and thumbs behind (Fig. 304). 2. The head is slowly bent backwards, the rest of the body being unmoved (Fig. 305). 3. The head is bent slowly forwards (Fig. 306). 4. The head is inclined to the right (Fig. 307). 5. The head is inclined to the left.

The commands would be given—
Boys (or *Girls*), *Atten—tion.*
For Head Exercise—One, &c.

This exercise should be repeated eight times. End with *Stand at—Ease.*

First Body Exercise.

From the position of attention, 1. Take the position shown in Fig. 308 by placing the hands on the hips and carrying the left foot 12 or 14 inches to the left. 2. Bend the body backwards as far as possible, the head being well thrown back and the knees kept stiff (Fig. 309). 3. Bend as far forwards as possible, the chest being well

out and head well back (Fig. 310). 4. Bend the body to the left (Fig. 311), and then to the right. 5. Resume the position of attention.

The commands are—

Boys (or *Girls*), *Atten—tion.*

For First Body Exercise—One, &c.

Repeat this exercise twelve times, and end with *Stand at—Ease.*

Fig. 304.

Fig. 305.

Fig. 306.

Fig. 307.

Second Body Exercise.

From the position of *attention* the following movements are to be performed:—1. Both arms are kept straight, the right is raised as high as possible above the head, *palm outwards*, and the left arm is stretched down, close to the side, as far as possible, shoulders being kept square to the front, back well hollowed so that the chest stands out, and the body well bent over to the

Fig. 308

Fig. 309.

Fig. 310.

Fig. 311.

left at the waist, the eyes looking to the right hand. 2. The right arm is brought down, and the left raised, the body being now bent over to the right, and the eyes turned to the left hand. 3. The left hand is now swung, *palm inwards*, sideways to the right, by a circular movement, and as it comes level with the right hand, both arms are raised high over the head, the backs

of the hands towards the face; the body is turned on the hips to the right and bent over to the left, the head being thrown back and the eyes looking to the backs of the hands. 4. Both arms are swung down by the front and up to the left, the body being turned to the left and

Fig. 312.

bent to the right (Fig. 312). 5. Resume the position of attention.

The commands for this exercise are—

Boys (*or Girls*), *Atten—tion.*

For First Body Exercise—One, &c.

Practise this exercise eight times, and end with *Stand at—Ease.*

Third Body Exercise.

From the position of attention, 1. Raise the arms as high as possible, palms outwards. 2. Bend quickly down and touch the ground in front of toes with the tips of the fingers, keeping the knees straight (Fig. 313). 3. Quickly straighten the body and then bend as far back as possible, the arms making a circular sweep till they are stretched beyond the head, palms outwards, the head being well thrown back and the eyes directed to the backs of the hands. 4. Straighten the body, and bring the arms to the position of attention.

Fig. 313.

The commands are—

Boys (*or Girls*), *Atten—tion.*

For Third Body Exercise—One, &c.

Practise this twelve times, and end with *Stand at—Ease.*

The special use of these exercises is to strengthen the great muscles passing up the back along each side of the spine (see p. 71), and the muscles passing between the trunk and the lower limbs, specially the psoas iliacus and glutei muscles, noted on p. 73.

First Leg Exercise.

From the position of attention, 1. Smartly raise the hands and place them on the hips, fingers to the front, thumbs to the rear, elbows and shoulders well forced back (Fig. 304). 2. Rise on the toes as high as possible, legs being kept straight (Fig. 314). 3. With the head erect and elbows well back, gradually lower the body, bending the knees, till the body just touches the heels, which latter must, as far as possible, be kept together, the knees being forced well apart (Fig. 315). 4. Raise the body, straightening the knees, without bringing the heels to the ground, and then lower the heels to the ground. 5. Resume the position of attention, the arms being dropped quickly to the side.

Fig. 314.

All the motions except 1 and 5 are to be performed slowly. In 2 and 3 the body must be kept upright.

The commands are—

Boys (*or Girls*), *Atten—tion.*

For First Leg Exercise—One, &c.

Repeat this twelve times, ending, as usual, with *Stand at—Ease.*

The second movement of this exercise brings into special activity the gastrocnemius muscle, which forms the calf of the leg and by whose contraction the heel is pulled up (see p. 74). Many other muscles are, of course, involved.

For instance, the knees are kept from yielding by the rectus muscle in front of the thigh (Plate II. 8 of fig. 3), while many muscles are concerned in keeping the balance. In the third movement the calf muscles are acting to keep

Fig. 315.

the heels off the ground, muscles in front of the thigh are acting to prevent sudden bending of the knee, and other muscles are on guard similarly at the hip, all this being done against the weight of the body, so that the work is considerable. In the fourth movement the straight muscle of the thigh acts strongly to straighten the leg and so on.

Second Leg Exercise.

From the position of attention, 1. Move the hands to a position behind the back, so that the left hand grasps the right arm just above the elbow, and the right hand supports the left arm under the elbow (Fig. 316). 2. Make a partial turn to the right, the right foot pointing to the right, and bring the back of the left heel against the inside of the right foot. The left foot should point straight to the front, and the right should be at right angles to it. The head should be erect, eyes directed to the front, shoulders pressed back and chest advanced (Fig. 317). 3. Take a full step to the front with the left foot, the right remaining flat on the ground. The right leg should be kept quite straight, the knee being well braced back, and the hips pressed forward. The left knee is bent, and is perpendicular to the instep. The body is kept upright and head erect (Fig. 318). 4. Bring the left foot back to the position of 2. 5. Face to the left, so that now the right foot points straight to the front, and the back of its heel is against the inside of the left foot. 6. Advance the right foot in the same way as the left was advanced. 7. Come back to the position of 5. 8. Resume the position of attention, from which the exercise started.

Fig. 316.

The commands will be understood from the orders given under previous exercises.

Fig. 317. Fig. 318.

Practise this movement twelve times, and end with *Stand at—Ease.*

Third Leg Exercise.

From the position of attention, 1. Make a full step to the left with the left foot, the right being kept flat to the ground, and the leg perfectly straight. 2. As soon as the left foot touches the ground, let the left hand grasp the thigh, just above the knee, thumb inside and fingers outside, the lower part of the left leg

and the left arm forming a straight line from the foot to the shoulder, the right arm remaining closely in line with the right leg (Fig. 319). 3. Turn on the heels so as to face the right,

Fig. 319.

and now make the left leg straight and let the left arm be stretched in line with it, and let the right leg and arm assume the position the left is seen to be in in the figure. 4. Return to attention in the original place.

Practise this twelve times, and end with *Stand at—Ease.*

Leg and Body and Arm Exercise.

From the position of attention, 1. Move the left foot 10 inches to the left and the right 10 inches to the right, heels being in line, toes pointing outwards, knees slightly bent, and arms hanging straight (Fig. 320)—the position of Fig. 308, but with the legs straight and the arms straight down in line with the legs. 2. Bend the knees till they project beyond the line of the toes, keeping the feet flat on the ground; at the same time bend from the waist and bring both hands to a position between the two feet, closed and placed against one another, knuckles touching the ground (Fig. 321). 3. Quickly straighten the back and legs, carry the arms close up by the sides till they are stretched above the head (Fig. 322). 4. Spring into position of attention.

Practise this sixteen times, ending with *Stand at—Ease.*

Such exercises as have been given in detail are useful only to a limited extent. They cause the various muscles involved to contract, but they give them little work to do. The only work the muscles perform is that of moving the part acted on against the resistance of its own weight. In bending the arm at the elbow, for example, the resistance is the weight of the forearm; in standing on tiptoe the resistance is the weight of the body. Now it has been found that, within certain limits, the more work a muscle has to do, the greater the resistance offered to its contraction, the better is the contraction, and the more valuable is the effect on the muscles themselves. While this is the case, it is not proper to put a heavy strain upon the muscles all at once, nor yet to tax them for a long time on end. The resistance should be small at first, and gradually increased till it reaches an amount, suited for the individual; and the exercise against this resistance should be continued for a short time to begin with, and the period gradually lengthened.

Fig. 320.

Fig. 321.

Fig. 322.

The weight of the body may be made use of to supply resistance for a few simple exercises. Thus let two chairs be placed about two feet apart; let the pupil, standing

between them, place one hand on each, and then step back, keeping the hands on the chairs till the arms are fully stretched; then gradually allow the arms to bend at the elbow till the body is lowered to the space between the chairs, the body being kept all the time rigid. The elbows should then be slowly straightened and the body raised. This is repeated several times. Or again, let the pupil stand between two supports, say school desks, two feet apart, one hand on each. Let him lift himself just off his feet by pressure through the arms, then bending his knees let him slowly lower himself till his knees touch the ground, and then slowly raise himself again. This he will not be able to accomplish all at once, but only gradually after repeated practice.

Dumb-bells are a simple means of giving the muscles work to do. Their weight should be in proportion to the capacity of the pupil, and can be increased in weight as the pupil's strength increases. For children it is recommended that they be made of wood, weighing for boys 1½ pounds each, for youths 2½ pounds. For adults they are made of iron and should be from 4 pounds upwards.

EXERCISES WITH DUMB-BELLS.

First Dumb-bell Exercise.

Let the pupils stand in a row in position of attention (Fig. 297), the bells together in front of the toes. Let the movements of the **First Arm Exercise** be then performed with the bells. At the command—*One*, the pupils bend the body, keeping the legs straight, and, seizing a bell in each hand, straighten the body, bending the elbows up to the position of 2 in Fig. 299, the bells being thus brought up to near the shoulder. At the command *Two*, the bells are raised above the head, the arms being fully stretched, and so on through the other movements of the First Arm Exercise.

The exercise should be repeated eight to twelve times, and, at the end, the command might be given *Down Bells*, at which the pupils would bend the body, keeping the legs straight, and having laid the bells down in front of the toes, would resume the position of attention. They could then get the order *Stand at—Ease.*

Second Dumb-bell Exercise.

This may be the **Second Arm Exercise**, performed with the bells in a way similar to the First Dumb-bell Exercise.

The teacher can thus take as a basis the exercises without apparatus and adapt them to movements with the bells.

The **Third Leg Exercise**, and the **Leg, Body and Arm Exercise** may be used for the bells as follows:

Third Dumb-bell Exercise.

The pupils stand in position of attention, the bells in front of the toes, and the following movements are performed: 1. Make a full step to the rear with the left foot, the right following. 2. Make a half turn to the right, and step to the front with the left foot, the left hand grasping the thigh above the knee, the knee being bent, the right leg being kept fully stretched, and the right arm in line with it as in Fig. 319. 3. Seize the right bell in the right

Fig. 323.

hand (Fig. 323) and raise it as high as possible above the head, the legs maintaining their position unchanged. The left arm is straightened, forming with the lower part of the left leg a straight line from foot to shoulder; and the hand presses firmly against the left knee, the breast being well pushed forward with the lifting of the bell (Fig. 324). 4. Replace the bell, the limbs keeping their position and then quickly spring back into position of attention.

This exercise is then repeated, from the other side, the body being turned to the left, the right foot stepping forward, and the bell being seized with the left hand.

Repeat this exercise from the right and left sides alternately sixteen times.

Fourth Dumb-bell Exercise.

From the position of attention, 1. The pupils take a full step to the rear with the left foot, the right following. 2. A half-turn to the right is taken, and then they step to the front with the left foot as in the last exercise; the body is bent over, the left knee yielding, the right leg being kept extended. Both hands pass down,

one on each side of the knee, each seizing a bell. 3. The bells are raised high above the head, the left knee being kept bent, and the right leg unmoved. 4. The bells are brought down and

Fig. 324.

Fig 325.

Fig. 326.

Fig. 327.

replaced in their original position. 5. The pupils spring back to attention.

This exercise is repeated, but the right foot is put forward, the body facing to the left.

Fifth Dumb-bell Exercise.

I. From the position of attention, 1. The pupils step to the rear as in the preceding exercise. 2. A partial turn to the right is taken, the right foot pointing to the right, the back of the left heel against the right instep as in the **Second Leg Exercise.** 3. They take a full step to the front with the left foot, the right remaining flat. The left knee is bent, the right leg is straight, and bending the body they seize the right bell with the right hand (Fig. 323). 4. The bell is raised high above the head and the body brought back to the position of 2 (Fig. 325). 5. They step again to the front with the left foot, lower the bell, and come back to the position of attention.

Fig. 328.

Fig. 329.

II. Repeat this exercise, the pupils turning to the left, putting the right foot forward, and lifting a bell with left hand, the movements being the same as those preceding, but the pupils acting from the left.

III. Repeat this exercise, advancing the left foot, but raising a bell with each hand (Fig. 326), stepping back with them into position of Fig. 327, stepping again to the front and lowering the bell, and lastly resuming the position of attention.

IV. Repeat the same exercise, advancing the right foot, and seizing a bell in each hand.

The teacher can easily distinguish the different parts of this exercise from one another. Thus his commands would run as follows:—

Boys (or *Girls*), *Atten—tion; For Fifth Dumb-bell Exercise; With one bell—from the right—One,* &c.

This would imply the first portion of the exercise; the second portion would be indicated by the caution—*from the left.* The third and

Fig. 330.

fourth portions would be indicated by the caution— *With two bells* and *from the right* (or *left*), as the case might be.

Fig. 332.

Sixth Dumb-bell Exercise.

This exercise is a repetition of the **Leg, Body, and Arm Exercise** (p. 767), but with the bells.

1. From the position of attention the position shown in Fig. 328 is assumed by the movements detailed on p. 767. 2. By the movements mentioned at the same place the bells are grasped, one in each hand (Fig. 329). 3. The bells are raised high above the head (Fig. 330). 4. The bells are lowered as in Fig. 329, and 5. The position of attention is resumed.

BAR-BELL EXERCISES.

The bar-bell is a rod of ash, 5 feet long, 1 inch

Fig. 331.

in diameter, and with a ball at each end. Exercises similar to those with the dumb-bell may be engaged in. Figs. 331, 332, and 333 illustrate

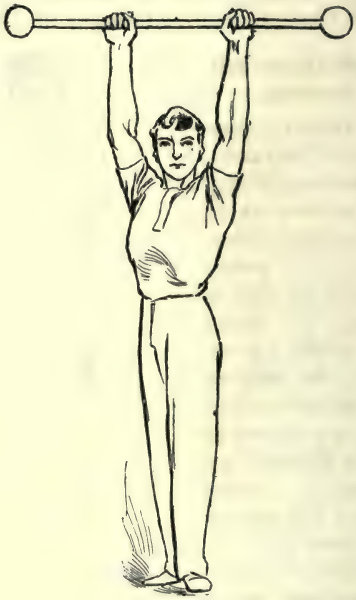

Fig. 333.

movements, the same as those of the **Third and Fourth Dumb-bell Exercises,** and the instructor can make use of other exercises which will readily suggest themselves.

Fig. 334.

Fig. 335.

Fig. 336.

HOOP EXERCISES.

For young children the hoop affords a variety of simple and useful exercises. The hoop should be light, 25 inches in diameter.

The teacher who has carefully studied the exercises without apparatus will be able easily to put together a few exercises, consisting of similar movements with the hoops in use, as the following figures show:—Figs. 334, 335, 336, 337, and 338.

Fig. 337.

Fig. 338.

The Use of Exercises in the Treatment of Disease: Massage.

Graduated Exercises in Disease. — The employment of exercises for the cure of disease, or what is called medical gymnastics, can, it appears, be traced back to the earliest times on record of the Hindoos and Chinese, and was in common use among the Greeks and Romans. Muscular pains and cramps, the results of muscular fatigue, neuralgias, spinal curvatures, were so treated, as well as dropsy and other diseases. In the beginning of the eighteenth century the methods, which had been long neglected, were

again brought into prominence by the publication of various works on the subject—one, in 1728, was by a London surgeon, Francis Fuller, called "Medicina Gymnastica"—but it remained for Ling to revive, or rather recreate the treatment, under the modern name of the "movement cure." Ling was led to believe in the possible benefit of muscular exercises by himself getting rid of a rheumatic affection of the arm by fencing. He set himself to study anatomy and physiology, and to investigate the value of definite movements on diseased states. In 1813 he first practised at Stockholm the curative movements. Of recent years, much more extended consideration has been given to the value of movements in disease, largely through the influence of pupils of Ling, and the applicability of such methods is now admitted in cases of rheumatism, neuralgia, sciatica, associated with another form of mechanical treatment called **massage**. Exercises, similar to those described on pp. 761 to 771, are employed, along with manipulations, by some one trained to their proper performance, of the kind described below, and along with what are called **passive movements**, that is movements of the patient's limbs, effected not by himself but by some person grasping the limb and causing the movement to be executed. Such treatment is found very useful, not only in the cases named, but also in sprains, inflammations of joints, stiffness of joints, in various nervous and digestive disorders, constipation, &c. In lateral curvature of the spine various simple exercises, without apparatus, are frequently sufficient to correct the deformity.

Massage is derived from the French *masser*, to knead, although kneading is only one of the manipulations employed in the process. It is not to be confounded with shampooing as practised by a bath attendant; and we are told that to acquire the art of properly giving a massage, implies much preliminary study and very prolonged and careful practice. The objects of massage are, in the first place, to influence the nutrition of the whole body, or a particular part of it, and, in the second place, to promote the removal of swellings, inflammatory products, &c., that disease may have occasioned in any particular place. It is comparatively easy to understand how these effects may be produced. When the masseur (*masseur* is the term applied to the male attendant who gives massage, *masseuse* to the female attendant), when the masseur rubs or strokes the skin, he immediately affects the circulation of blood through it. As his fingers pass over the skin, stroking it with some degree of firmness, he empties the blood-vessels, and when the pressure has passed the blood fills the vessels again with a rush. If he strokes always in the direction of the current, as he ought always to do—from the extremities towards the heart, never backwards and forwards in a random way—the assistance to the circulation is material. But he influences also the lymphatic vessels (p. 200), the vessels by which in particular the products of waste are removed, and he thus stimulates the removal of injurious substances. When he picks up the skin and rolls it, as it were, between finger and thumb, he does the same things more effectually. When he administers a brisk tap or slap with one or two fingers, or with the flat of the hand, the stimulus is again marked, for the skin immediately reddens. Then the masseur also ought to be acquainted with anatomy; he ought to be able to separate out with his fingers a single muscle or a small group of muscles, and treat them in a like way, through the skin, stroking them, squeezing them, kneading them, prodding them with the points of his fingers, or with the edge of his hand, and so stimulating the blood current to them, aiding and hastening the removal of waste from them, and exciting them to contraction. He ought to know the direction in which large vessels run, and the regions in which nerve trunks lie, and he ought to be able to insinuate his fingers between muscles to reach and act upon them also. All this is well fitted profoundly to affect the nutrition of the parts acted upon, and not them only, but also the rest of the body, through the circulation and the nervous system, and is very different from the few minutes' shampoo in the Turkish bath.

A variety of terms is used to indicate the kinds of manipulation employed, such as stroking, rubbing, kneading, pinching, pressing, squeezing, hacking. In some books the French words are used—*friction*, which explains itself, and *effleurage* both apply to the skin, the latter being the movement of rolling the skin between the fingers; *tapotement*, or tapping, and *petrissage*, or kneading, are the means by which deeper structures are reached.

General massage implies that the whole body is treated; partial massage means that it is restricted to some particular part. Half an hour to one hour is the time devoted each day to the process. The process should be performed on the naked skin by the bare hands of the operator, no oil being used; and the hands ought to be strong and firm, but soft, very considerable exertion being expended in the process.

The process is thus described by Dr. Weir Mitchell: "The patient lying in bed, the manipulator starts at the feet, and gently but firmly seizes the skin, rolling it lightly between his fingers, and going carefully over the whole foot; then the toes are bent and moved about in every direction, and next, with the thumb and fingers, the little muscles of the foot are kneaded more largely, and the interosseous groups (see p. 73) worked at with the finger-tips, between the bones. At last the whole tissues of the foot are seized with both hands and somewhat firmly rolled about. Next the ankles are dealt with in like fashion, all the crevices between the articulating bones being sought out and kneaded, while the joint is put in every possible position. The leg is next treated, first as to the skin, then by deeper grasping of the areolar tissue, and last by industrious and more profound pinching of the large muscular masses, which, for this purpose, are put in a position of the utmost relaxation. The grasp of the muscles should be firm, and for the large muscles of the calf and thigh both hands should act together, the masses of muscle being, as it were, twisted around the bone, while the hands alternately contract on them. In treating the firm muscles in front of the leg, the fingers or the two thumbs are made to roll the muscle under the cushions of the finger-tips. At brief intervals the manipulator seizes the limb in both hands, and lightly runs the grasp upwards, and then returns to kneading the muscles.

"The same process is carried on in every part of the body, and special care is given to the muscles of the loins and spine, while usually the face is not touched. The abdomen is first treated by pinching the skin, then by deeply grasping and rolling the muscular wall in the hands, and at last the entire belly is kneaded with the heel of the hand in a succession of rapid deep movements passing round in the direction of the colon (see Fig. 87, p. 131), while somewhat later the whole belly, relaxed by position, may be shaken by a rapid motion of the grasping hands. Pinching or squeezing of the skin is very valuable in certain spinal troubles connected with increased sensation, and in some other cases, if the surface and extremities be very cold; but the best masseuses often omit it, and rely solely upon the deeper grip and rolling of the muscles. The process should not be painful, or more at first than merely fatiguing; but after a time the muscles may be handled with a good deal of strength, without causing other than agreeable results. Too much care cannot be used to cover with stockings and warm wraps the parts after in turn they have been subjected to massage. As to time: at first the massage should last half an hour, but should be increased in a week to a full hour. Sometimes I use it twice a day, but commonly one hour suffices. Women who have a sensitive abdominal surface have, of course, to be handled with care, but in a few days a practised rubber will by degrees intrude on the tender regions, and will end by kneading them with all desirable force. The same remarks apply to the spine when it is hurt by a touch; and it is very rare indeed to find persons whose irritable spots cannot at last be rubbed and kneaded to their permanent profit. The daily massage is kept up through at least six weeks."

Massage has yielded its most remarkable results in cases of nervous disorder of a hysterical kind, in cases of wasting through imperfect nutrition, dependent upon some disturbance of stomach, bowels, or liver, and it has proved valuable in some of the special diseases of women, and in diabetes, while paralysed and contracted muscles are often wonderfully benefited by it.

SECTION VII.—CLIMATE AND HEALTH RESORTS.

Climate.

What is Climate?

Temperature as it affects Climate;
Temperature as modified by Elevation above Sea-level;
The Influence of Prevailing Winds;
The Effect of Position of Mountain Ranges;
The Influence of Ocean Currents;
The Meaning of Mean Temperature, &c.;
Moisture of Air as it affects Climate;
Rainfall.

Effects of Climate in Health:

Effects of Excessive Heat and Cold;
Effects of Humidity;
Winds and Atmospheric Pressure.

Effects of Climate in Disease:

Climate suited for Diseases of Lungs and Air Passages—Consumption, Bronchitis, and Asthma, and Climates suited for them;
Climates suited for Heart Affections;
Climates suitable in Diseases of Kidneys and other Abdominal Organs;
Climates suited for Malaria;
Climates for Nervous Diseases;
The Climates for Scrofula and General Diseases.

Health Resorts.

British Health Resorts:

The Isle of Wight, the Undercliff, Ventnor;
Bournemouth, Weymouth, Sidmouth, Exmouth;
Teignmouth, Torquay, Dawlish, Salcombe, Penzance, and Falmouth;
The Channel Islands; The Scilly Isles;
Brighton, Eastbourne, St. Leonard's, and Hastings;
Hythe, Sandgate, Folkestone, Dover, Ramsgate, and Margate;
Yarmouth, Lowestoft, Scarborough, Whitby, Redcar, Saltburn;
Bude, Barnstaple, Ilfracombe;
Aberystwith, Barmouth, Beaumaris, and Llandudno;
Southport, New Brighton, Blackpool, Isle of Man;
Rothesay and Bridge of Allan and other Scottish Resorts;
Queenstown, Glengariff, and other Irish Seaside Resorts.

Mediterranean Health Resorts:

The Western Riviera—San Remo, Mentone, Monaco, Nice, Cannes, Hyères, Genoa—Their Characteristics, and the Diseases for which their Climate is suitable;
Malaga, Ajaccio.

Other European Resorts:

Pau, Biarritz, Arcachon;
Coasts of Norway, Sweden, &c.;
Alpine Climates—Davos Platz, St. Moritz, Meran, Tarasp.

Atlantic Islands:

Madeira, The Canary or Fortunate Islands, The Azores.

African Health Resorts:

Algiers, Egypt, South Africa.

American Health Resorts:

California—San Diego, San José, &c.;
Florida; The Bahamas and Bermuda;
Colorado—Denver, Manitou Springs, Colorado Springs.

Indian Health Resorts:

The Hill Stations.

Australian Health Resorts:

Queensland (Brisbane), New South Wales (Sydney), Victoria (Melbourne), South Australia (Adelaide), Western Australia (Perth), Tasmania (Hobart Town), New Zealand (Auckland, Christchurch, Dunedin).

CLIMATE.

What is Climate?—The word climate is derived from the Greek, *clima*, a tract or region, and was applied to a portion of the earth included between two circles parallel to the equator. Different regions vary, according to their distance from the equator, in the amount of sun heat and light received, and in other attendant circumstances. Thus the word has come to imply, not the portion of the earth's surface itself, but its condition in relation to sunshine, temperature, character composition and moisture of the air, rainfall, wind, and similar circumstances, in their bearing upon life, and, in particular, human life. The climate of a place is determined principally by the duration of its exposure to the sun's rays, and this depends on its nearness to the equator. A large number of local conditions, however, operate as secondary, but, nevertheless, important factors in modifying this chief element and giving to a climate its distinguishing characters. The principal local conditions are the presence of mountain ranges, proximity to the sea, or, in inland districts, to rivers or lakes, height above sea-level, nature of the soil and vegetation, and so on. The chief of these factors in the production of climate we must give some little consideration to.

Temperature as it affects Climate.—It is the heat derived from the sun that determines the temperature of any place. The circumstances which directly affect the quantity of heat received from the sun by any place are the nearness of the earth to the sun and the direction in which the sun's rays fall upon the place. The latter is much more important than the former. In our mid-winter, owing to the elliptical orbit of the earth, the sun is distant from us more than 3,000,000 of miles *less* than in midsummer, and the lessened degree of heat at the former period, in spite of the increased nearness to the sun, is due to the oblique direction of the rays as they reach us, while in midsummer the rays fall more perpendicularly. Similarly it is at the period of the day when the sun is directly overhead that the greatest degree of heat is experienced. Now we have pointed out (p. 681) that the atmosphere is not directly heated by the sun's rays. The radiant heat from the sun passes through the air without perceptibly warming it, because the air does not absorb heat readily. This is very noticeable where the air is very clear and dry. Thus, on board a whaler, the rays falling on the deck have heated the pitch to the point of making it bubble out of the seams, while, in the shade, ice was forming on the ship's side. The rays falling upon the earth heat it, however, and heat it in proportion to its power of absorbing heat. The earth being heated will warm the layer of the atmosphere in contact with it, this layer becoming lighter by increase of heat will rise, and a cold layer will flow in to take its place, to be in turn warmed, and so on. The temperature of a place, while directly influenced by the exposure to the sun's rays and the direction in which these rays fall, is thus very powerfully influenced by the nature of the soil and its capacity for receiving and giving out heat, since it is only through this process that the atmosphere of the place is warmed. If the surface layer of the earth at the particular place is a good conductor of heat, the heat received by that layer will be conducted downwards into the earth for some distance, and to the extent to which the soil conducts well will the atmosphere have a less chance of becoming excessively warm, since air is a bad conductor. If, on the other hand, the soil is of badly conducting material, the heat will not readily pass downwards, and the atmosphere will receive more heat from the soil. Rocky surfaces conduct well, so also do clay and loamy soils, and the heat does not, therefore, accumulate so much on the surface of such soils. Sand, on the other hand, is a bad conductor of heat, and during exposure to the sun's rays becomes excessively warm. It also has a very high absorbing power for heat, absorbing nearly double the amount of heat that earth (mould) will. Consequently, owing to both these circumstances, the atmosphere over sandy deserts becomes oppressively hot, "the surface temperature of sandy deserts of the tropics rising frequently to 120°, 140°, and more rarely 200°." Moreover, the amount and nature of the vegetation of the district will have a modifying influence on the temperature, for vegetation will protect the soil from the sun's rays to some extent, and by evaporation from leaves, &c., will prevent the temperature of the surface rising so high as it would otherwise do. In a climate of a country covered with vegetation one does not, therefore, find the same extensive variation of temperature within twenty-four hours as is found in a country without vegetation, the vegetation keeping the district cooler during the hottest part of the day than it would otherwise be.

Now during the time that the sun's rays are

being poured upon a district, the temperature of the surface layers of the earth is rising, because they are receiving more heat than they are giving out. They are, however, giving out heat to the atmosphere in contact with them, whose temperature is rising also. But when the sun has set, and sometime before then, the earth is receiving little heat and is giving out much, its temperature is therefore falling. During the sunny parts of the day, that is to say, the earth is storing heat, and during the sunless parts of the twenty-four hours it is distributing it. If a great deal is stored and slowly given out there will not be marked extremes of temperature in twenty-four hours, very hot by day and becoming suddenly cold by night, but the heat will be more evenly distributed during the twenty-four hours and a more equable climate will result. As an illustration of this we have already instanced the effects of vegetation. Forests have a very striking effect of this kind. "Trees are heated and cooled by solar and nocturnal radiation in the same manner as other bodies. They do not, however, acquire their maximum temperature till a little after sunset. This occurs in summer at 9 p.m., while in the air the maximum temperature occurs between 2 and 3 p.m. Hence trees may be conceived as reservoirs in which the heat of the day is stored up against the cold of the night. Changes of temperature take place very slowly in the tree, but in the air they are very rapid. Hence the effect of forests on the daily temperature is to make the nights warmer and the days colder, or to give to the climate of countries clad with trees something of the character of an insular climate" (Buchan). Another excellent illustration of the same thing is the modifying influence of large masses of water. Water, it has already been pointed out, has a greater capacity for heat than any other substance. The same quantity of heat will not raise its temperature so high as it will that of other substances. Moreover radiant heat from the sun can penetrate to some depth into water, and thus the ocean, inland lakes, &c., can receive enormous quantities of heat, without their temperature being raised nearly to the same extent as land receiving equal quantities. These circumstances produce most marked modifying effects on the climate of localities by the sea, lake, or river. The surface of the sea being never heated by the sun's rays to the same extent as the surface of the land bordering it, the atmosphere in contact with the sea will be cooler than that in contact with the land, and thus a current will be established from sea to land—a sea breeze—which will keep the land cool. In the evening the land cools down much more rapidly than the sea, for the surface of the sea cannot, like the surface of the land, cool down more quickly than its deeper layers. As soon as the surface layer becomes cool it sinks, and is replaced by warmer water rising. The atmosphere over the land will, in consequence, become speedily colder than that over the sea, so that a land breeze will be created. In this case the warmer air from the sea will prevent the too rapid cooling of the general atmosphere. Thus during the day the climate will be less hot and during the night less cold than it would be, but for the modifying influences of the sea. Inland lakes have a similar effect though not nearly so marked, but when they are frozen over the influence ceases. In such circumstances as these, there is a period of the afternoon when the sea breeze begins to die down, because, owing to the setting sun, the land is less warmed and its air becomes more nearly like that of the sea in temperature. Between that period and the commencement of the land breeze, perhaps two or three hours later, when the earth has cooled sufficiently, there is a period of calm; and there is similarly a calm in the morning between the dying down of the land breeze and the setting in of that from the sea.

In another way does the presence of large masses of water influence the climate of a place. Wherever there is much water the air must contain a considerable degree of moisture because of evaporation from the surface, another agent in keeping down the temperature. Now while perfectly dry air will not absorb the solar rays as they pass through it—is transparent to heat, or diathermanous, as the correct word is—watery vapour does absorb heat to some extent. Moist air does, therefore, become warmer by the sun's rays passing through it, dry air does not. Moreover, when the heat is being given off from the earth at night, it will pass off much more rapidly if the air is dry and clear than if it is moist. There will, therefore, be less rapid cooling of the air at night in a locality where the air is moist to a greater or less degree. A moist atmosphere is heated to some degree not only by the sun's rays passing through it, but also to a considerable extent by rays reflected back into the atmosphere from the earth, for the earth does not retain or absorb all the rays that fall upon it. Now if the air were perfectly dry, these reflected rays would pass through the atmosphere without warming

it, but when the air contains watery vapour, the watery particles absorb the reflected heat and thus retain, in the neighbourhood of the ground, heat, which would otherwise have been dissipated into space. The presence of clouds in the sky diminishes the loss of heat at night by radiating back to the earth the heat given off by it, and the lower the clouds are the more effective are they in maintaining the heat. It is this which explains the sultry oppressive feeling of the atmosphere on the evening of a hot summer day when the sky is dull.

Elevation above the Sea-level has a striking effect on the temperature of a place. As elevation increases, the temperature falls. The cause of this is mainly that the atmosphere is warmed by contact with the earth, and not by the direct action of the sun's rays. The higher the situation the more is the locality, in the cold regions of the atmosphere, removed from the warming influences of the earth's surface. At the same time the heating effect of the sun's direct rays becomes more perceptible in high situations, because the clearness of the air, and its freedom from fog and moisture, permit the full heat of the sun to play upon the body, &c., without let or hindrance. Thus, in high altitudes, in the sun one may be scorched, while in the shade one may be freezing. The more elevated the situation, then, the more is it deprived of such modifying influences as have been noted in preceding paragraphs, such as proximity to masses of water, watery vapour in the air, and so on. In consequence the variations of temperature are extreme and sudden. As a general rule the fall in temperature for increasing elevation is 1° Fahr. for each 300 feet of ascent. There is what at first sight looks like a very remarkable exception to this rule that temperature falls with increasing height, namely, that, at night, in calm dry clear weather, and in frosty weather, localities situated on a height are actually at a *higher* temperature than those in the valley. The reason of this is that, after sunset, the heat radiates rapidly from the earth, and the layer of air in contact with the chilled surface becomes in turn quickly cooled down. This cooled air being denser than the warmer air above it remains low-lying. In the case of hill slopes and valley, other circumstances being equal, the air in contact with the surface of the hillside will also be cooled down, and then owing to its increased density will flow down to fill the valley, while warmer air will supply its place on the slope. The cold of the night and of frost will, therefore, be felt less on the slope of the hill than at its foot. In the mind's eye one can picture, on a clear frosty night, the cold air currents flowing down the hillsides, like so many streams of water, into the valley, till the plain beneath is completely submerged beneath a sea of cold air, rising higher and higher, but above which the more elevated parts of the slope remain in warmer air. This is a point worth remembering in fixing upon a place of residence in an undulating country.

Prevailing Winds modify the temperature of localities very markedly. The warm westerly and south-westerly winds, for example, of our own climate, laden with moisture, raise the temperature of the western side of the British islands. If the winds blow from the direction of mountain ranges which are so high as to be perpetually capped with snow, they will depress the temperature; while if they come from the direction of hot, sandy deserts, they will raise the temperature. Winds blowing from the sea necessarily carry a considerable quantity of moisture, and this moist air, passing over a district exposed to the full blaze of a burning sun, will moderate the temperature of the place by the screen the watery vapour interposes in the path of the heat rays. On the other hand, passing over a cold region, the same moist wind will raise the temperature by diminishing the loss of heat by radiation from the surface of the earth, and by the deposition of its moisture liberating the heat which the water held in a latent condition while in a state of vapour. Moist ocean winds are, then, cooling in summer and warming in winter. On the other hand, dry winds blowing from continents raise the temperature in summer and lower it in winter.

The Position of Mountain Ranges, Hills, &c., is most important as an influence in determining the warmth of any particular locality. The hills may act as a barrier to cold winds. An excellent example of this is San Remo, the well-known Mediterranean health resort. Its prevailing winds are northerly, but it is guarded by a semicircle of mountains of the Maritime Alps. Though these ranges are interposed as a baffle-plate, as it were, between the cold north and north-east winds, which are thus deflected upwards, high over the sheltered piece of coast-line, so that they never strike the town, they yet have an effect upon the temperature, preventing it becoming excessive. The situation of a locality in relation to mountain gorges, valleys, &c., is another illustration of the same fact. For example, there is a considerable difference in warmth between the eastern and

western bays of Mentone, due to the fact that the mountain shelter of the eastern bay is complete, while, on the western bay, there are open valleys of the mountain range, down which the cold winds more readily sweep. Mountain ranges, hills, &c., may also serve to keep a locality cold if by their situation they screen it from the sun's rays.

The Influence of Ocean Currents in determining temperature is illustrated by the effect of the most important of such currents, that of the Gulf-stream, on the climate of Western Europe. "If no more heat is received than is due to the position of the globe in respect of latitude, the mean winter temperature of Shetland would be only 3° and that of London 17°. But, chiefly owing to the heat given out by the Gulf-stream during winter, and carried to these places by the winds, their winter temperatures are respectively 39° and 37°—Shetland being thus benefited 36° and London 20° from their proximity to the warm waters of the Atlantic. In Iceland and the Norwegian coast, the increase thus accruing to the winter temperature is much greater. To these places the Atlantic may be conceived as a vast repository of heat, in which the warmth of the summer months, and that of more southern regions, are treasured up and reserved against the rigours of winter" (Buchan). But for this stream the British climate would be fully 20° colder in winter than it is. "As regards their influence on climate," says Buchan, summarizing the results of Admiral Fitzroy's observations, "ocean currents raise the temperature of the west of Europe, the east of South America, the east of Africa, and the south of Asia; and depress the temperature on the east and west coasts of North America, the west coast of South America, the west coast of Africa, the east coast of Asia, and the south coast of Australia."

Other circumstances affect the temperature of a locality which it is scarcely necessary to consider at length. We may notice, for example, the form and colour of hills, cliffs, &c. The form of hills partially surrounding a locality may be such as to cause the sun's rays, reflected from them, to be concentrated on the place, and specially will this occur if white cliffs, rocks, &c., form part of the range, by which the reflection would be much greater.

The Meaning of Mean Temperature, &c. —There are certain technical expressions employed in describing the temperature of localities, which, in view of their subsequent use, it may be well to explain here. In the first place, the distinction between "heat in the sun," or "sun heat," and "heat in the shade," or "shade heat," should be noticed. The latter is the heat of the air, direct rays of the sun being prevented falling upon the thermometer, as well as rays reflected from any surface in its neighbourhood. The thermometer is usually exposed to the air in a louvre-boarded box, at a height of four feet from the ground, at a distance from walls or objects likely to be heated by the sun, and over old grass freely exposed during the day to the sun. The former expression, "sun heat," is applied to the heat obtained near the surface of the ground in such a position that the rays of the sun fall directly upon the bulb of the thermometer, which is coated with lamp-black to enable it to absorb as much heat as possible.

The mean daily temperature is obtained by observing the temperature every hour, summing the results and dividing by 24, or by observing the highest temperature of the day, obtained by the maximum thermometer, and the lowest temperature of the day, obtained by the minimum thermometer, and taking their mean. The latter is now adopted and need imply only two daily observations, one at 9 a.m. and the second at 9 p.m. From these mean temperatures, the mean temperature of a week, a month, or a year may easily be calculated. The **mean annual temperature** is not of very high value in estimating the value of any locality as a health resort. Two places might have the same mean annual temperature, but that of one might be composed of a low winter temperature compensated for by a high degree of summer heat, while that of the other might be made up of a winter temperature not low and a summer temperature not high. The former climate would have extremes of heat and cold, the latter extremes of neither. For estimating the value of a climate for health purposes, then, it is best to obtain the mean temperatures for the seasons, spring, summer, &c., or still better the mean temperatures of the months. In the same way two places may show the same mean *daily* temperature, but one may enjoy a temperature which varies by only a few degrees in the twenty-four hours, while the other may have excessively hot days followed by very cold nights—made up of two extremes, that is to say. Obviously the former is more suitable from a health point of view. Therefore, to enable one to estimate the suitableness of a locality, one seeks to know not only the mean monthly or daily temperatures, but also the two elements

which go to form the mean daily temperature, the highest and lowest temperature of the twenty-four hours. "Thus in the north-west parts of the United States of America the temperature in spring often rises to 83° during the day, and falls to freezing during the night." This would give a mean temperature of 57°·5, which, it is apparent, if stated by itself would give an altogether erroneous impression.

The difference between the extreme day and night temperatures is called the **range of temperature**, and the less the range the more equable is the climate.

In this country temperature is stated according to **Fahrenheit's scale**—freezing point 32°, boiling point 212°. On the Continent the **Centigrade or Celsius' scale** is employed—freezing point 0°, boiling point 100°. It may be well to note how these may be converted, the one into the other. To convert Centigrade into Fahrenheit, multiply by 9, divide by 5, and add 32.

$$\text{Thus, } 100^\circ \text{ Centigrade} = \tfrac{900}{5} + 32 = 180 + 32 = 212^\circ \text{ Fahrenheit.}$$

To convert Fahrenheit into Centigrade, subtract 32, multiply the remainder by 5, and divide by 9.

$$\text{Thus, } 212^\circ \text{ Fahrenheit} = (212 - 32)\tfrac{5}{9} = 180\tfrac{5}{9} = \tfrac{900}{9} = 100^\circ \text{ Centigrade.}$$

Moisture of Air as it affects Climate.—Next to the temperature of the air, the amount of watery vapour the air contains is one of the most important circumstances affecting the climate of a locality. The difference between a dry climate and a humid climate is a difference only in degree, since all air contains some watery vapour. This has already been mentioned in discussing air on p. 682. It has been there explained that the capacity of air for absorbing moisture increases with its warmth. When air contains as much moisture as it can hold at a given temperature it is said to be saturated; and if the air then becomes cooled it must give up some of its moisture, which then becomes deposited in the form of dew, or falls as rain. Thus in the evening, when the sun has set, the heat rapidly passes off by radiation from the earth, and the surface of the ground becomes cooled. The air in contact with it, becoming thereby in turn cooler, is unable to retain all its moisture, and the excess is deposited as dew, the amount deposited being dependent on the amount of watery vapour in the air and the degree of cooling to which it is subject. The more rapidly, therefore, substances are cooled, the more speedily will dew be formed upon them, and the greater will be the amount deposited on them. Furs, wool, flax, silk, grass, and vegetable substances generally, cool more rapidly than gravel, stone, and sand, and on them more dew will appear. The cooling of the earth's surface is hindered by clouds, and the more effectually the lower the clouds are, for they radiate back to the earth the heat it gives off, so that a clear night is necessary for dew formation. Wind also hinders it, for it circulates the air and prevents the cold layer next the earth being formed. So also warm currents of air, laden with moisture, rising in the atmosphere and meeting with colder masses, are compelled to yield up a portion of their watery vapour, which then descends as rain or snow. Certain winds are, therefore, always accompanied by rain, since they bring with them, into colder latitudes, warmer moist currents, such as the south-west wind in our climate.

The air derives its moisture by evaporation as it passes over the surface of water and moist places. The warmer the wind is, the greater will be the amount of water picked up by it in its course. The actual amount of watery vapour held by a certain quantity of air is called its **absolute humidity**, but the quantity it holds in relation to the quantity it is capable of holding, at the given temperature, is called its **relative humidity**. Of two equal masses of air, both containing the same amount of watery vapour, but one of higher temperature than the other, the warmer will seem to be actually drier, because by its higher temperature it is capable of holding more water in the state of vapour than the other. It will not be so near its point of saturation as the colder mass of air; its relative humidity, that is to say, will be smaller. So that two masses of air may contain absolutely the same quantity of watery vapour, and yet one be called very damp and the other dry, because the former is colder than the latter. The relative humidity of air is expressed in terms of 100; that is, saturation is called 100; so that air whose humidity is 70 is $\frac{7}{10}$ths saturated. At sea, at night, the humidity of the air approaches saturation; in the interior of continents, amid dry sandy deserts, it falls very low. It is low at the hottest parts of the day and the hottest seasons of the year, and is high at night and in winter, in each case because of the temperature of the air.

The effects of the degree of humidity of the atmosphere on climate have already been alluded to in speaking of temperature. An atmosphere

rich in moisture, however clear and transparent it may appear to the eye to be, greatly intercepts the radiant heat of the sun on its way to the earth. The watery vapour absorbs the radiant heat, so that less reaches the earth than would were the air more nearly dry. In the same way the heat of the earth is not given off so rapidly by night when the air is moist; its radiation is checked. Heat is thus more slowly acquired during the day and more slowly parted with during the night. This cooling influence by day and warming effect by night aid in minimizing sudden alternations of temperature, and help to secure a more equal distribution of heat during the twenty-four hours. This effect may, however, become excessive, so that the atmosphere is sultry and depressing and wanting in exhilarating character. But wherever the moisture is deficient, in countries exposed to the full blaze of the sun, the heat is burning throughout the day and the nights may be bitter with cold. "In mountainous countries where, on account of their height, much less aqueous vapour is interposed between them and the cold regions of space, radiation, both solar and terrestrial, is least obstructed. It is this which explains the scorching heat that surprises the Alpine tourist while travelling over fields of snow under a blazing noon-day sun. And it is the same cause, the small amount of vapour in the air, that explains the intense heat experienced in the direct rays of the sun in the polar regions."

Rainfall is a matter of great importance from the point of view of the person seeking a desirable climate. But amount of rainfall is not of so much value as an indication, as the record of the number of days on which the rain fell. Thus the rainfall may be enormous at one portion of the year, and much smaller during the remainder. At Madras, for example, the rainfall during the wet season, October, November, and December, is 30 inches, and for the other nine months of the year only 19 inches. At Gibraltar 33 inches fell in 26 hours, at Genoa 30 inches in 24 hours, and on the Khasia Hills, north-west of Calcutta, 30 inches fell on each of five successive days. This latter was due to the southerly winds, soaked with moisture from the Indian Ocean, being forced to yield up the water by the hills driving them up into the higher and colder regions of the air. For the chief determining causes of a rainfall are winds laden with moisture, from passing over a sea or ocean, being deflected upwards into the colder regions of the atmosphere by ranges of hills opposing their level course. These are the conditions on the west coasts of Great Britain, Ireland, France, Norway, Spain, and Portugal. The prevailing winds being south-west, they lick up moisture from the Atlantic, and the rainfall is, therefore, considerable in the immediate neighbourhood of high hills. On the other hand winds passing over sandy deserts, continents, &c., are dry.

The number of rainy days increases with the distance from the equator. In the northern hemisphere between 12° and 43° of latitude the average number of rainy days in the year is 78, while it is 103 between 43° and 46° of latitude, 134 between 46° and 50° latitude, and 161 beween 50° and 60° latitude.

Many other circumstances go to the determination of the characters of the climate of any locality—the prevailing winds and the exposure of the locality to them, or its protection by hills, liability to mists, fogs, &c., cultivation of the soil, drainage, &c., which need not be further considered.

Effects of Climate in Health.—**The effects of excessive heat and cold** upon health, from a climatic point of view, it is not possible to state with certainty, so much do other circumstances, such as those connected with food, exercise, humidity of the air, &c., influence the results. Tropical heat tends to raise the temperature of the body of those coming from temperate climates, but the increase does not exceed 2° Fahrenheit, and this is in time diminished by the increased action of the skin. This increased activity of the skin induces the eruption known as prickly heat, because of the great determination of blood to the skin rendered necessary. Breathing is affected, the respirations being lowered, and the total action of the lungs being diminished, so that less carbonic acid gas is given out. This is doubtless the result of lessened combustion going on in the body, since a much less production of heat in the body is called for, and of the rarefaction of the air causing less oxygen to be supplied from the atmosphere. The heart-beats are also diminished, it would appear. Corresponding to the diminished need of the internal production of heat, there is a lessened demand for food, less appetite, though an increased desire for water, because of the need of liquids to make good the evaporation from the surface. The digestive powers are also diminished, perhaps because of the determination of blood to the skin. In fact, general bodily and mental vigour is depressed

in the case of persons belonging to a temperate climate proceeding to the tropics, though this is probably also a mixed result, dependent not only on the high temperature, but also on other conditions of the atmosphere, such as diminished oxygen, &c. It is generally believed that Europeans from temperate climates "do not flourish in countries much hotter, that is with a yearly mean of 20° Fahr. higher, as in many parts of India; that the race dwindles and finally dies out; and therefore that no acclimatisation of race occurs. And certainly it would appear that, in India, there is some evidence to show that the pure race, if not intermixed with the native, does not reach beyond the third generation. Yet it seems only right to say, that so many circumstances besides heat and the other elements of climate have been acting on the English race in India, that any conclusion opposed to acclimatisation must be considered as based on scanty evidence. We have not gauged on a large scale the effects of climate pure and simple, uncomplicated with malaria, bad diet, and other influences adverse to health and longevity" (Parkes). It is quite certain that the evil effects, ascribed so exclusively to the excessive degree of heat, have been largely due to the continuance of food, stimulants, and clothing, suited to temperate regions, but not adapted to the hot climate. A distinction is to be made between the heat due to the direct rays of the sun, **the heat in the sun**, and the heat of the atmosphere itself, **heat in the shade**. The latter is much less easily borne, because the hot air contains usually moisture, and the same degree of evaporation from the skin is not possible. Thus a sun heat of 120° can be endured when a shade heat of 90° to 100° is overpowering.

More moderate degrees of heat than that obtaining in tropical countries have similar effects in stimulating the skin and in diminishing appetite, respiration, and tissue change, but to a lessened extent. Persons who seek warmer climates, on account of weak health, do not usually seek warmth merely, do not seek, that is to say, simply to avoid cold, but also to avoid exposure to great variations in temperature; they seek to obtain a more uniform climate, to get rid of very pronounced currents of air which sudden changes of heat produce. It is to be noticed also that persons of weak general health require moderate degrees of heat to maintain the normal functions of body and mind, and that in their case the change to a warm climate is accompanied by a stimulus to the processes of life instead of a depression. In such persons the vital powers are already so depressed, that a degree of cold, which would exert only a quickening influence on the healthy body, almost paralyses them.

As to the effect of cold, it in general acts, on the healthy body, in a manner the reverse of heat, quickening the circulation, quickening digestion, improving the appetite, and accelerating tissue change. Provided appropriate food be forthcoming, all this is beneficial. By the healthy and vigorous, excessive cold is quite easily borne, being met by proper food and clothing. Supplied with these, the European, going from a temperate climate to the Arctic regions, can endure the cold and maintain his bodily warmth, while in a hot climate no device may enable him to keep cool. It is, of course, different with the delicate, in whom the diminished activity of the skin, by leading to the withdrawal of the blood to the deeper organs, is apt to occasion or maintain diseased states of lungs, kidneys, &c.

The effect of the degree of humidity of the air in health depends on the increased evaporating power of dry air and the diminished power of moist air. A dry air will encourage evaporation from the skin and lungs. But the air may be so dry, as in the case of the dry sirocco, that this becomes excessive, leading to harshness and dryness of the skin. The evaporating power, it is to be remembered, is to be considered not only in relation to the amount of moisture in the air but also to the temperature of the air, for a dry cold air will not absorb so much moisture as a dry warm air. In dry warm air the skin is specially stirred to activity, because of the flow of blood to it, to yield fluid for evaporation for maintaining the bodily heat at its proper level. When the dry air is cold, the skin is not so excited, since the blood is directed from the skin to the deep organs to prevent loss of heat from the surface, and it is the lungs which feel the stimulus. When the air is moist, on the other hand, the exhalation from both lungs and skin is lessened and a soothing rather than a stimulating influence is produced. When the air, in addition to being moist is warm, depression of the vital processes is the result, and oppression may be the result of the difficulty encountered by the skin of maintaining the balance of bodily temperature. Moist heat is one of the favourable conditions for the growth of putrefactive and other germs. In such circumstances diseases such as cholera, typhoid fever, diarrhœas, consumption, flourish. But when the air is at once moist and cold,

chilling of the surface of the body results, because of the moisture aiding the conduction of heat from the body. Colds and rheumatic affections are likely to arise, and catarrhal states of the air-passages, such as bronchitis, and of the kidneys, are often induced.

Winds are to be counted as beneficial or injurious to health according to their characters, moisture, and so on, and their force. Complete absence of wind is not healthy, since the absence of atmospheric currents means the want of due admixture of the air, specially necessary in populated places. High winds, whether hot or cold, dry or moist, are injurious to health. In Great Britain the east winds of winter and spring, from their dry and piercing character, are powerful agents in raising the mortality.

As regards the pressure of the atmosphere, changes in it and their effects on health have been already referred to on p. 680.

The Effects of Climate in Disease will be seen, from what has been said, to be a very mixed problem. It is not a mere question of removing an invalid from a place of low to one of higher temperature, or the reverse; a great many other factors enter into the question. The effects of heat, as we have seen, cannot be dissociated from the effects of atmospheric moisture, nor can these be considered apart from the effects of atmospheric pressure as it affects, among other things, the quantity of oxygen in the air. Then one cannot afford to overlook the fact of the presence or absence of foreign materials in the air, such as dust raised by winds, materials due to industries of the district, and, of still more importance, foreign particles of organized kind such as depend upon the proximity of marshes, the drainage of the soil, the nature of the vegetation, the character and habits of life of those native to the locality. Still further, in considering the effects of climate in the treatment of disease, one must not overlook the facilities afforded by various localities, or the reverse, for exercise, the probabilities of a great deal of outdoor life being possible because of equability of climate, and freedom from violent winds and sudden surprises by variation of temperature or rapid alternation of sunshine and rain. Not only must the possibilities of exercise be taken into account, but also inducements to exercise, because of the natural beauties of the locality or artificially created attractions. Finally, before any invalid decides upon a climate where he may hopefully seek restored health and renewed vigour, the possibility of adequate and suitable accommodation being readily obtained, with safety from risk of encountering other diseases, must be settled. The drainage and water-supply of many health resorts were for a long time of so primitive a description, and the conditions of life of the inhabitants so careless of sanitary laws, that the seeker after health too often found disease, of a more serious and debilitating character than that from which he sought relief. Happily so much public attention has of recent years been directed to these subjects that such risks are much less than they used to be, especially in the case of the most favoured health resorts. So complicated then is the influence which the climate of any particular place may have on a person suffering from ill-health, and so greatly will the total effect depend upon the actual condition of the patient at the time, that it is very often impossible to predict very exactly what kind of climate will suit him, so that he may be compelled to try one locality after another before finding that which he seeks. Moreover the climate suitable for a patient in one phase of a disease may prove very unsuitable at another. How often does a person, suffering from some chronic disease, who is in the habit of regularly visiting some particular health resort and always with benefit, suddenly at some subsequent visit find that he is no longer benefited, and that he must set out again in quest of a more congenial climate.

If then we proceed to consider what are the general requirements in the way of climate that seem indicated in the chief of the ailments for which change is sought, and the principal places where they are to be found, it must be understood that no absolute statement can be made, and that each invalid can have the question of climate settled for him only by a very careful study of his own condition and all that it seems to demand. We shall begin such consideration of climate, as suited to particular diseases, by taking that class of diseases which provides probably the greatest number of those who seek change, namely sufferers from diseases of the lungs and air-passages.

Climate suited for Diseases of Lungs and Air-passages.—No class of diseases exemplifies more fully the truth of what has been said regarding the difficulty of settling the question of suitable climate than this class. The requirements for such diseases are a pure air, a temperature not subject to great or sudden alternations, abundance of sunshine, plentiful opportunities for exercise, but whether it should be moist or dry, bracing and stimulating or soothing, depends upon the nature of each case.

For Consumption of the Lungs a great variety of climate has been recommended. Dr. C. T. Williams, a high authority on the subject, gives the following statistics of consumptives who passed one or more winters out of England with their results:—

		Percentages.	
		Much Improved and Improved.	Worse.
Sea voyages to Australia, America, India, China, the Cape and West Indies	45 winters	89	5·5
Very dry climates; Egypt and Syria	26 ,,	65	10
,, ,, Cape and Natal	13 ,,	58·6	17·24
South of Europe and Mediterranean Basin, &c.	152 patients	62·5	17·1
Rome	18 ,,	55·56	33·33
Warm Atlantic Islands, Madeira, Teneriffe, St. Helena, West Indies	70 ,,	51·43	34·29
Calm moist inland temperate climate, Pau, Bagnères de Bigorre..	44 ,,	50	45·45.

In this table the highest place is assigned to sea voyages, and the next to *dry* climates. Moist warm climates are the least beneficial, if not on the whole actually injurious. The cases most suitable for a sea voyage are those in which the disease is in its early stage, and it is the most appropriate means of treating the disease when it is but suspected, when the tendency exists, and when the desire is to guard against it if possible. The best route is that to Australia, when the voyage lasts ninety days, which allows time for the patient getting rid of any preliminary sea-sickness and becoming used to the life of ship-board. If, however, there is risk of protracted sea-sickness, it would be an indication against the voyage. The beginning of October is the time to set sail, Australia being reached early in January, and the return voyage should be begun not later than the close of February. The interval should be spent in the table-land of New South Wales, or in Queensland, or New Zealand, or in cruising, residence in the coast towns being avoided on account of the heat. The return may be made by the Suez Canal or Cape of Good Hope.

Dry *inland* climates like those of Egypt and South Africa are preferred where the marine stations prove too stimulating, and tend to produce undue excitement. The Mediterranean health resorts, such as those of the Riviera, Mentone, San Remo, Cannes, Nice, specially the two former, and Algiers, are at once dry and stimulating, and are suitable for a large number of respiratory affections. But acute cases ought not to be sent thither.

British patients, who can meet the moderate expense of change of air to a not too distant locality, but whose resources would be taxed by so far a journey as the Mediterranean, or whose strength seems scarcely adequate to the travelling, will find Ventnor, in the Isle of Wight, and other stations in the south and south-west of England, such as Hastings and Bournemouth, very suitable. These localities, according to Dr. Williams, are to be preferred to Torquay and Penzance. Regarding Ventnor, Dr. Hill Hassall has supplied some instructive statistics, derived from the reports of the Hospital for Consumption and Diseases of the Chest, established by him there. In the four years 1870 to 1873, 474 patients were treated, of whom 122 were improved, 161 much improved, 83 very much improved; 28 were restored; 34 were in much the same condition as when they entered; 22 became worse; and only 24 died. In 1878, of 501 patients admitted during the year, 106 were improved; 78 became much better, 150 very much better; 53 were restored; 36 remained in much the same condition; 62 became worse, and only 16 died.

The treatment of consumption by a residence in mountain climates has of recent years been brought prominently before the medical profession. While safety from consumption is nowhere absolute, certain striking facts have been brought forward regarding the mortality from consumption among Swiss natives living regularly at certain levels. Thus in the case of those living at a level of from 1250 to 1650 feet above the sea, consumption was the cause of 10·2 per cent of the total deaths. The mortality at a height of from 1725 to 2700 feet was, from the same cause, 9·4 per cent. In the high regions, 2700 to 4000 feet, the mortality fell to 5·1 per cent, while above 5000 feet the disease totally disappears. In the Upper Engadine (5000 to 6000 feet), and at Davos Platz, consumption is said to be unknown among those who have always lived there. "Above a height of 8000 feet, in the Peruvian Andes, phthisis (consumption) is almost unknown among natives; while in the coast lands in the same country it is common and rapidly fatal." Now in these high altitudes it is not warmth that is sought, for in the health resorts of the Alps the temperature is low, and the season is in winter,

from the middle of October to the end of March, the snow lying on the ground to a depth of 2 or 3 feet throughout that period. Still, in the direct rays of the sun, it is sometimes as warm as the midsummer of temperate climates. But the air is, if cold, very dry, and not liable to fluctuation; the sky is clear; and, owing to the bright sunshine, patients can be out of doors for most of the day, as they could not be in lower localities. The low temperature of the air, unfavourable as it is to putrefaction and to the propagation of the life of minute organisms, has probably something to do with the healthy influence. Undoubtedly another element in the beneficial effect is the low atmospheric pressure and consequent diminished density of the air. The effect of this is to produce expansion of the chest with accompanying expansion of the lungs. The effect of the climate of such altitudes is stimulating, both on heart and lungs, and also on the digestive organs; and there is consequent general improvement of nutrition. Nevertheless, all cases of consumption are not suited for such climates. Many could not bear the stimulating action of the high mountain air. The proper cases are specially those in the early stage, or those in a later stage, but not acute, where the disease is not extensive, and the patients have a good circulation and are able for a fair amount of exercise. Where there is risk of bleeding from the lungs the case is not suitable. In suitable cases complete arrest of the disease is often obtained.

The chief mountain resorts at present are the Swiss Alps, specially Davos Platz, 5140 feet above the sea-level, the Peruvian Andes, Santa Fé de Bogota, in New Granada, 8648 feet, a climate remarkable for equability, being 59° Fahr. in winter and 49°·5 in summer, Manitou Springs (6315 feet), Colorado Springs (5775 feet), and Denver (about 5000 feet), in the Rocky Mountains.

In regard to a summer health resort, the following are the conditions most suitable for the majority of consumptive cases, as stated by Dr. Hill Hassall: "The air should be dry, cool, moderately equable, but not cold; and the difference between day and night temperature should not be too considerable; the situation should be sunny, the sun neither reaching it too late in the day nor leaving it too early, as is the case with many of the mountain health resorts now in fashion; the elevation should not be too great, two, three, or at the most four thousand feet. I have known persons who have been sent to the Engadine suffer greatly in their breathing, even in summer, from the rarefaction of the air at that elevation, the difficulty being further increased by the great difference between the day and night temperature, and the cold of the early morning and afternoon as contrasted with the almost tropical midday heat."

In the lung condition known as emphysema (see p. 283) mountain climates are not to be recommended, but a mild not too dry resort, if possible in the neighbourhood of pine-woods. Arcachon, on the west coast of France, is recommended.

Bronchitis and other catarrhal affections of the respiratory organs, throat affections, &c., require climates similar to those already described for consumption, with the exception of those of high altitude. To those already named Hyères, in the south of France, may be added, and Arcachon, which lies south-west of Bordeaux. For chronic bronchitis, with much expectoration, dry climates are more suitable, while where the air-passages are irritable, and the expectoration is slight, a more moist locality is desired. Of the latter class Madeira may be taken as typical, which is noted for its soothing effect in irritable cough, allaying it in a very remarkable manner. In relaxed conditions of the system, however, with copious discharge, it is the reverse of suitable. The Azores and the Canary Islands are suitable in cases for which Madeira is. Teneriffe is the principal island of the latter group, and Orotava, a town on its north-western side, is provided with better accommodation than the capital, Santa Cruz. They are winter resorts; but at Orotava higher elevations are accessible, where in summer the excessive heat may be avoided. The English watering-places, Hastings, Ventnor, Torquay, may also be found useful.

Asthma.—The sufferer from asthma must in very many cases determine for himself what suits him best. Asthmatics are so commonly affected by the nature of the vegetation, that the patient is often driven from place to place, finding one place suit him at one season, and another at another season, according to the flowering time of certain plants. If the disease has been contracted in a moist climate, a dry one should be tried, and if it has been contracted inland, the sea-side may be resorted to. Mountain climates are very often useful; Madeira, and the Canary Islands, Pau, in the department of the Lower Pyrénées, and any of the climates already named as suitable for consumption may be found to yield benefit. In

Scotland, Forres, the hydropathic establishment of which is situated in the midst of a pine-wood, has a high repute for asthmatics.

The climate suited for heart affections is one rather bracing in character, moderately dry. Sudden changes of temperature, cold, and damp, are specially to be avoided. High altitudes are unsuited.

For diseases of the kidneys the climate must be warm and dry. The best for this purpose are Upper Egypt, Bombay, Cape of Good Hope, the Riviera, and in England Brighton, Folkestone, and Ventnor. Mountain climates are unsuited, and so are all moist climates. The latter diminish instead of stimulating the activity of the skin, and it is by the extra activity of the skin that the diseased organs are relieved. All cold and damp climates, by chilling the surface of the body and sending the blood to the deeper organs, are hurtful in such diseases.

Diseases of other abdominal organs will find suitable climate on the Mediterranean shore, or in the Lower Engadine, where Tarasp is specially recommended for the bilious and dyspeptic subject, the victim of chronic dysentery, or of nervous disorder consequent upon overwork. St. Moritz in the Upper Engadine is a favourite resort for sufferers from digestive derangements and sluggish circulation. For such disorders also the bracing influence of sea air is valuable, such as may be obtained in the health resorts of the south of England, Hastings, and Ventnor, or on the Irish coast, Queenstown. The association of baths and mineral waters with the climatic treatment is of great benefit in all disturbances of the abdominal organs, specially such as are attended by sluggish liver, constipation, &c., and the appropriate baths are noted in the part devoted to medicines. For feminine complaints the same thing is true.

The climate for malaria is that of high elevations, and bracing sea-side resorts, such as those of England.

The climate for nervous diseases varies according as the treatment indicated is of a stimulating or soothing character. Of the latter Arcachon in France is recommended for the calming and yet tonic action of the pine-woods, and dry inland climates, such as those of Upper Egypt, and the districts of Cannes away from the sea. Pau, in the Lower Pyrénées, is advantageous because of its calm atmosphere, which is very soothing to those of an irritable temperament, in whom nervous excitability is pronounced. Hyères is also advised in similar circumstances, Pisa in Tuscany, Venice, and Ischl in Austria. Biarritz, near Bayonne, on the west coast of France, is more bracing and exhilarating, being exposed to the winds and the influence of the Atlantic. Also, as a change from the more sedative climates, moderate mountain climates may be selected in summer. Nervous disorder, the result of overwork and worry, is best treated by a sea-voyage and the bracing influence of the sea-side resorts of temperate climates, such as the east coast of Scotland or the coasts of Ireland, or that of the island of Heligoland in the German Ocean.

The climate for scrofula ought to be one by the sea-shore, such as abound in the British Islands, the south and south-west in winter, and the east in summer; of the former Brighton, Isle of Wight, Bournemouth, and in Scotland Rothesay, and of the latter Scarborough, Lowestoft, the south coast of Fife in Scotland, or by Stonehaven in Aberdeenshire. Of the foreign resorts Algiers, Biarritz, Sicily are the chief.

In diseases of the general system and in convalescence from acute disease the Riviera is generally selected in winter and some more bracing mountain or sea air in summer. In England the health resorts of the south coast, and in Scotland Bridge of Allan, and Rothesay in Bute, are the winter resorts.

HEALTH RESORTS.

We shall now proceed to indicate a few of the chief features of some of the principal and best known health resorts, and any facts which may be of value to those in search of change of air and scene, in aiding their decision.

Various classifications have been proposed for climates. For instance one might divide climates into tropical, temperate, and arctic, a classification based on latitude. This would be of little use in indicating those suitable in the treatment of disease. Dr. Hermann Weber adopts two great divisions—Marine Climates (Island and Sea-coast), and Inland Climates. He classifies the former according as they are humid, or moderately humid, or dry, and the latter as mountain and lowland. Probably the purpose of those who consult this book will be best served if, without adopting any classification, we simply note various health resorts according to their geographical position, according to the country to which they belong.

British Health Resorts.

We have noted that the winter temperature of Great Britain is dependent upon the warmth

brought to its shores by the Gulf-stream and the winds blowing from it. As might be expected it is the west coasts that benefit to the greatest degree by this influence. The lines of equal temperature run north and south, not across the islands, in winter, the temperature all along the east coast being 37°, while along the west coast it is 39° and 40° and rises to 42° and 43° in the south-west of England. "Since the temperature of the whole of the eastern slope of Great Britain is the same, it is evident that to those for whom a milder winter climate is required, a journey southward is followed by no practical advantage, unless directed to the west coast. And as the temperature on the west is uniform from Shetland to Wales, Scotland is as favourable to weak constitutions during winter as any part of England, except the south-west. The temperature on the south-west of England and Ireland being, however, 4° higher than the west of Scotland, the mildest climates, and therefore the most suitable resorts for invalids who require a mild climate, are to be found from the Isle of Wight westward, round the Cornish peninsula to the Bristol Channel, and from Carnsore Point in Ireland to Galway Bay" (Buchan). This region is characterized by its mild character and the shelter from the north and east, while its southern exposure and sea influence make it a very suitable region for winter resort.

The Isle of Wight is one of the most important of the winter health resorts in the region named. The Undercliff, on the south-east portion of the island, a landslip which forms a kind of terrace, about six miles long and half to three-quarters of a mile wide, is the chief part. It is protected from the north, north-east, north-west, west and south-west, by lofty downs of chalk and limestone, so that it is open directly only to the south, south-east, and obliquely to the south and south-west. In this district are **Bonchurch, Ventnor,** and **St. Lawrence.** "From and including Bonchurch, to the village of St. Lawrence beyond Ventnor, we have the most favoured and best protected portion of the Undercliff district, and the best adapted for the winter residence of the delicate; as we advance more to the west, the protection is less as a whole, though undoubtedly equal to that of the eastern Undercliff, in many of the sheltered little nooks. Moreover, owing to its elevation above the level of the sea, the Undercliff differs from most situations on our coast, in being less exposed to the direct and immediate influence of the sea-air" (Sir James Clark). Ventnor is built on a series of terraces, varying in elevation from 400 to 700 feet, and this affords a variety of climatic condition dependent upon the elevation. The mean winter temperature of the Undercliff is 42°·14, and the mean daily range 10°; the average annual rainfall is 26·23 inches, and the number of rainy days 144.

The climate is well suited for general conditions of ill-health, scrofula, anæmia, &c., in convalescence from acute disease, in chronic catarrh of the throat and upper air-passages, and in cases where the tendency to consumption is feared. The soil is dry, and the place has the great advantage of affording abundant space for outdoor exercise, amid picturesque scenery.

Bournemouth, which is situated on a bay at the south-western extremity of Hampshire, is one of the most favoured of English health resorts. It is sheltered by extensive fir plantations, growing on surrounding slopes. The soil is sandy, and though this is of advantage by rapidly draining off surface water, in summer high winds blow clouds of it in a very disagreeable fashion. Its mean annual temperature is 49°·4, and it is blessed with a large amount of sunlight, and out-door exercise is agreeable. It is sheltered from the north, north-east, and partly from the east, but is less protected than the Undercliff and Torquay, though its temperature is somewhat lower than that of these places, while its atmosphere is less depressing. "There are two descriptions of persons to whom this climate offers great advantages," says Dr. Aitkin, "though neither may be said to labour under actual disease. In the first place, to persons who have long been resident in hot climates, and whose constitutions have, consequently, undergone changes that render them peculiarly susceptible of morbid impressions, resulting from the cold and dampness which prevail over by far the greater part of Great Britain. In the second place, to the young, who either from hereditary or accidental causes are of a weak habit of body, and whose tender and delicate constitutions, though unaffected with actual disease, yet are a constant source of apprehension and anxiety to their parents." It is a suitable place specially for delicate, sickly and rickety children, to whom its sands afford ample scope for amusement and exercise, while it is not unsuited for consumptive patients who are able to take a fair amount of exercise. The effect of the exhalations from its pine plantations is believed to be salutary in lung affections.

Weymouth, or **Melcombe Regis,** also with excellent sands and well protected by the bay,

Sidmouth, open to the south but sheltered from the north, north-west, east, and partially from the north-east, resembling Torquay, though somewhat colder, **Exmouth** and **Teignmouth**, are the chief places, as one travels westwards from Bournemouth till Torquay is reached. Sidmouth, Exmouth and Teignmouth are specially summer resorts, the last two being insufficiently sheltered, and not suited as climates for lung complaints during winter, because of this as well as because of a too variable temperature, while their bracing character makes them valuable resorts in summer. Exmouth consists of an old town, situated on a hill and exposed to high winds, and a new town more sheltered, but damp from its proximity to the river.

Torquay is celebrated for its mild climate and equable temperature. Situated on the north-east corner of Torbay, and surrounded by hills, which shelter it from north and north-west winds and in great measure also from north-east, and situated in one of the most beautiful districts of Devon, it presents to the invalid manifold attractions. Its mean winter temperature is 44°, higher, according to Mr. Vivian, than that of any other place in Great Britain; its annual rainfall is 28·2 inches, and the average annual number of rainy days 132. Its climate is not only warm and mild in comparison with many other places, but its characteristic is dryness, as compared with other parts of South Devon, supposed to be due to its position between two streams, the Dart and the Teign, which draw off the moisture, or to the limestone rocks, or the elevation of Dartmoor. The autumn and winter months are the least dry. The town is built on sites of varying elevation, the slopes being covered with villas, and thus, while the lower levels are mild and relaxing, more bracing atmosphere can be had within the limits of the town itself. It is a favourite place for persons suffering from general debility, for whom it is eminently suited, as a winter resort, and for consumptives, for whom, however, its moist air is scarcely to be commended if they can seek drier climates, though it is recommended in chronic bronchitis, pleurisy and asthma.

Dawlish, not far from Exmouth, is sheltered from the north and north-west, but open to the east, and is hence not a desirable place in spring.

Salcombe, further westwards than Torquay, is warm enough to permit the myrtle, lemon, orange, and aloe, to flourish naturally, and is said to be the warmest place on the south coast. It is, however, moist and relaxing, and the accommodation is restricted and room for exercise limited.

Penzance, on the shore of Mount's Bay, is the principal health station of the Land's End district. It faces the east, but is sheltered from western gales. It is 5° warmer in winter than London, and its temperature is equable, having a mean daily range of 6° as contrasted with 11° in London. Its winter temperature is less cold by many degrees than that of any other part of the kingdom, except Torquay, being 44°. The winter, however, if mild, is wet and the summer cool and moist, producing a feeling of languor and depression, so that its influence is decidedly sedative. The average rainfall is 44·66 inches, and the average annual number of rainy days 178. "In April and May it is decidedly inferior to the more sheltered spots on the south coast of Devon, and to the Undercliff" (Clark).

Falmouth, 30 miles eastwards, has a similar climate.

The Channel Islands possess a moist, equable climate, like that of the south-west coast of England generally. They are, however, exposed to high winds, and are subject in spring to the piercing north-east winds, so that they are rather summer than winter resorts. The climate is soothing and relaxing, as all warm moist climates are, and not suitable for patients who need a bracing air, such as those suffering from nervous or physical depression. Rheumatism prevails in Jersey.

The Scilly Islands, 42 miles from Penzance, and 25 from Land's End, possess the most equable winter temperature in the British Islands, if not in all Europe, according to Dr. Tripe. The mean temperature from November to March is 47°·9, but the moisture of the atmosphere is high.

Brighton, Eastbourne, St. Leonards and Hastings, on the south-east coast, are favourite summer resorts, as well as providing for suitable cases a winter climate.

Brighton extends along the coast for three miles, and its eastern and western portions differ considerably. The eastern portion is dry and bracing, the western more mild and damp. Sir James Clark says "delicate, nervous invalids generally feel better in the western part. Those, on the other hand, who suffer from a relaxed state of the system enjoy their health more fully in the eastern district. . . . Compared with other parts of the south coast, the climate of Brighton appears to the greatest advantage in the autumn and the early part of winter, when

it is somewhat milder and more steady than that of Hastings. Accordingly in all cases in which a dry and mild air proves beneficial, Brighton, during this period of the year, deserves preference over every other part of this coast. In the spring, on the other hand, owing to its exposure to the north-easterly winds, the climate is cold, harsh, and irritating to delicate constitutions. At this season, therefore, sensitive invalids generally, and more especially persons with delicate chests, should avoid Brighton." In summer it is a most attractive sea-side resort. The summer season is from June to the middle of October. March, April, and May are the worst months for invalids, so that from October to March is the appropriate winter season.

Hastings and with it **St. Leonards** are suitable for the consumptive to an extent resembling the Undercliff of the Isle of Wight. They are sheltered by tall cliffs, 300 to 600 feet in height, from the north, north-east, and north-west, less so from the east, the exposure being thus south and south-west. Hastings is more soft and sheltered than St. Leonards. The lower parts of the town are more under shelter than the higher, and therefore warmer. From the beginning of November to the end of March is the appropriate season, during which the mean temperature is 41°·4. The soil is dry, sand overlying clay. Of Hastings Sir James Clark says: "As might be expected from its low and sheltered situation, it affords a favourable residence generally to invalids labouring under diseases of the chest; hence delicate persons, who require to avoid exposure to the north-east winds, may pass the cold season here with advantage. But in recommending Hastings as a residence in such cases, it will be necessary to take into consideration the full influence of the sea-air; for, owing to the close manner in which this place is hemmed in on the sea by steep and high cliffs, it has an atmosphere more completely marine than almost any other part of this coast, with the exception of St. Leonards. Judging from my own experience, I should say that the climate of Hastings is unfavourable in nervous complaints, more especially in nervous headaches, connected with, or entirely dependent upon, an irritable condition of the digestive organs, and also in cases where a disposition to apoplexy and epilepsy has been manifested. But it will be understood from what has been already stated respecting the topographical relations of Hastings, that this effect of its climate is chiefly experienced in the lower and more confined parts—nor is such an effect peculiar to this place, it is common, I believe, to all places similarly situated. The class of persons alluded to, if induced to reside for any length of time at Hastings, should avoid the more confined situations below the cliff, and rather seek such quarters as are more open and elevated, yet in some degree protected from north and north-east winds. These remarks on the climate of Hastings apply to it as a winter residence; as a summer residence the more open and exposed situations should be sought, and for many persons the high grounds behind Hastings would be preferable to the lower situations close to the shore." Dr. Hermann Weber says of it that as a winter climate it is less suitable for those requiring shelter, warmth, and a humid and equable atmosphere, but cases of atonic gout and rheumatism, and atonic catarrh of the mucous membranes, and tendency to colds from weakness, and atony (weakness) of the skin are generally benefited during the months of October to February. St. Leonards is not so warm for a winter residence; it is more blowy, more exposed to the east, less equable and more bracing. At both there is an excellent beach for sea-bathing, very bright, attractive, and bracing for children. Both places have the supreme advantage of offering to the visitor every kind of accommodation, convenience, amusement, and luxury.

The health stations situated farther to the east, **Hythe, Sandgate, Folkestone, Dover, Ramsgate, Margate,** are more suited for summer residences, and need not be considered here.

The east coast of England, like the east coast of Scotland, possesses many admirable watering-places, whose bracing tonic air is eminently fitted for the tired-out man of business or literary worker.

Yarmouth in Norfolk, **Lowestoft** in Suffolk, **Scarborough** and **Whitby, Redcar** and **Saltburn** in Yorkshire, are examples.

On the west coast of England **Bude,** on the north coast of Cornwall, **Barnstaple** and **Ilfracombe** on the North Devon coast, are examples of watering-places, not quite suited for winter residence for invalids because of their exposure, and not too bracing in summer.

The Welsh watering-places, **Aberystwith, Barmouth, Beaumaris** on Anglesea, and **Llandudno,** all partake of the same general characters, mild and humid, and they are all exposed to the westerly winds, except the last, which is sheltered by the Great Orme's Head from the west, north-west, and north, and by another and a lower range from the south and south-east. It

is a possible health resort for those who can endure some amount of wind.

Southport, New Brighton, Blackpool, on the north-west coast of England, are excellent summer seaside resorts.

The Isle of Man, Dr. Weber says, deserves to be more appreciated. Its summer climate is more bracing than that of any locality near the western coast, and the sea-bathing is very good.

Scotland possesses two chief winter health resorts, Rothesay and Bridge of Allan.

Rothesay is situated on the Island of Bute, which is 18 miles long and 4 to 6 broad. It is surrounded on all sides by hills of the opposite coasts. Its temperature never falls low in winter nor rises high in summer, but its climate, though mild and equable, is very humid. It is excellently suited in the winter and spring months for the invalid who desires shelter from the cold of the season, but is not suffering from any particular disease; but it is too depressing and relaxing in summer for most people. "Every part of Bute is not equally mild during winter. The eastern is much milder than the northern coast, owing to its being in some measure protected from the influence of the north wind. The climate of this island may be styled as mild and equable, but rather humid. It resembles in character that of the south-west of England and France, and of the Channel Islands, though it is considerably less warm than any of these. As a winter residence for invalids it holds out considerable advantages to that class only for whom a soft, equable, but rather humid atmosphere, is indicated." Anyone with chest affections should not try it unless under medical advice. The accommodation and bathing facilities are all that could be wished.

Bridge of Allan, within a short distance of Stirling, is built on sloping ground well wooded, which protects it from the east wind. "From its sheltered position, the east wind passes over it at a reduced rate and force, and there being consequently less evaporation, our bodies are deprived of less heat, and thus the sensation of greater warmth which we feel is a reality. Again, being built on rising ground, the cold air flows down to the valley below it, so that excessive cold rarely occurs" (Buchan). The climate of Bridge of Allan is suited for the same class of cases as Rothesay.

If Scotland is poor in winter health resorts, "the whole land 'frae Maiden Kirk to John-o'-Groats,' is itself one great health resort for summer, when from early June to the late days of October, the stream of tourists pours unceasingly by glens and mountains, by lakes and rivers, such as few lands can excel for beauty." All along the east coast are to be found watering-places, unrivalled for their facilities for sea-bathing because of the long stretches of sandy shore, affording a bracing invigorating climate, though practically unsheltered from the winds. North Berwick on the southern shore of the Firth of Forth, Elie on the opposite coast, St. Andrews on the north-east coast of Fife, and the shores of Aberdeenshire are examples of seaside resorts of a stimulating and innerving character.

The west coast of Scotland is less bracing in summer, but is cooler and is more humid.

Of the health resorts of Ireland **Queenstown,** on the southern portion of the Island of Cove, in Cork Harbour, is suitable in winter under the same conditions that make the winter resorts of the southern coast of England advisable. It has a very mild and equable climate, has a southern exposure, but is sheltered from the north. Its mean winter temperature is 44°·21, and spring 50°·17. It is not suitable for anyone to whom a moist somewhat relaxing climate might prove injurious. In asthma and chronic bronchitis, with irritable cough, it has been recommended; but it is too moist, as a rule, for consumptive patients.

Glengariff, off Bantry Bay, is of similar characters and of much natural beauty.

In general it may be said of Irish as it is said of the most of the British seaside resorts that their equability of temperature, their relative warmth—a feature, as already pointed out, of all climates, whose dominating influence is the ocean—make them useful to those who do not require special protection; but that their high degree of moisture render them unsuitable in serious lung and kidney affections specially, as well as in rheumatic and gouty conditions. In scrofulous conditions, in convalescence from acute diseases and from surgical operations, and in persons in the enjoyment of fairly good constitutions, but suffering from overwork and strain, whether mental or physical, with fair digestive power and not liable to nervous irritability, they are to be recommended. The eastern coasts, it may be accepted as a general rule, are drier and colder, and the western warmer and more moist, but with a duller atmosphere. It is only on the western portion of the south coast of England that there are to be found climates with fairly dry atmosphere.

Another marked point of contrast between them and the health resorts of the Mediter-

ranean, considered in the succeeding paragraphs, is the large number of rainy days they have annually, and the distribution of the rainfall throughout the whole year, so that days without rain cannot be reckoned on. Then the number of hours during which the rain continues on each day is more than in the more favoured southern climates. This is illustrated in the next paragraphs more fully.

Mediterranean Health Resorts.

The Western Riviera.—In the following paragraphs we shall consider very briefly only the best known of the health resorts of the northern shores of the Mediterranean. The chief of these are Hyères, Cannes, Nice, Monaco, Mentone, San Remo, the group which belongs to the district known as the Western Riviera.

The great characteristic of these localities is warmth accompanied by moderate dryness. They are more or less completely sheltered from northerly winds by the mountain chains of the Maritime Alps, though the different parts of the district vary in this respect, according to their proximity to gorges and valleys in the mountains, down which the cold winds may sweep. The soil is dry, the higher mountains being limestone. The mean annual temperature is about 60° Fahrenheit, Mentone being 60°·93, San Remo 60°·13, and Cannes 59°·9. Now that of the Undercliff, Isle of Wight, is nearly 9° less, and Bournemouth fully 11°. The mean winter temperature is 48°·98 in Mentone, 7° higher than that of the Undercliff. The thermometer rarely falls below 29° or 30° at night. The temperature in the sun is very great, but, notwithstanding, the daily range of temperature is comparatively small, being on a mean between 9° and 10°, for San Remo it is given as 9°·22. This is in consequence of three circumstances: first, the Mediterranean Sea, which equalizes the temperature, the explanation of which is given on p. 776; second, the sea breeze which prevails throughout the day, and thus cools the atmosphere at its hottest period; and third, the proximity of the mountains, which absorb the heat during the day, and radiate it at night upon the district, acting, as it has been said, like a warming plate to the shore. The number of sunny days is five times greater than in London. In Mentone, according to one authority, they averaged 214 in the year, 45·7 being partly sunshiny, 24·8 cloudy, and 80·8 rainy. Fog and mist are rare. The rain falls chiefly in September, October, and March. The number of rainy days per year of the chief resorts of the Riviera, and their contrast with other well-known places, are given by Dr. Hassall as follows:—

San Remo	48
Mentone	80
Nice	70 or 60
Cannes	70
Hyères	63
Pau	119
Malaga	40
Madeira	88
Ventnor	174·6
Bournemouth	156·3
Torquay	200

The atmospheric moisture is over 20 degrees less than in London, and it is the comparative dryness of the air that is one of the chief features of this district. The district is protected from the direct impact of the north winds by the mountain barrier. Nevertheless it is to their cold and dry characters that are attributed the clearness of the atmosphere and brilliance of sunshine. The wind which plagues these Mediterranean shores is the north-west or "Mistral." "It is a steady violent north-west wind which blows from France down on the Gulf of Lyons. It is immediately caused by the low atmospheric pressure in the Gulf of Lyons, as compared with the pressure to the north, and is most severe when at the same time very high pressures occur from France northwards towards the Arctic regions," which draw over the northern shores of the Mediterranean the polar current in its full strength, which becomes still colder and drier in crossing the Alps in its southward course. Such is Dr. Buchan's explanation. This wind is felt less at San Remo than at Cannes and Nice. While sheltered to the north, the Riviera is open to the south and south-west winds. It is to these that rain is due, bearing moisture as they do from the Atlantic as well as the Mediterranean. The south-east wind from the African deserts, as it strikes the southern coasts of Italy, is the Sirocco. Hot from the desert, but having swept up moisture from the sea, it comes as an exhausting wind. "It is the plague of the two Sicilies; and while it lasts, a haze obscures the atmosphere, and so great is the fatigue which it occasions that the streets of Palermo become quite deserted." Before it reaches the Riviera, however, it is cooled, and deprived of much of its evil influence, by the Italian mountains, but it is still felt sometimes as very warm and enervating. The mistral blows principally in March but occasionally also in winter and spring. The sirocco "blows only now and then for some days, and is then

almost always followed by heavy rain." The north-east wind is felt at the Eastern Riviera more than at the Western and is cold and biting.

As regards the most suitable period of the year for this climate, we quote the following from Dr. Hassall, who takes San Remo as a type of the district, and speaks from his own experience: "First, I recommend the intending visitor not to delay his departure from England too long, lest he take cold and his health be injured, but to leave it by the 1st of October, even if he do not come straight to San Remo, but spend a few days on the way; reaching it not later than the middle of the month, by which time the autumnal rains will usually be over and a period of dry and fine weather be expected. With regard to departure, this should be postponed as long as possible, and it should certainly not take place earlier than the middle or better still the end of May. The weather during the spring and early summer is usually most beautiful and enjoyable, being by no means hot. It is in the spring months that the patient usually derives the greatest amount of benefit from his sojourn abroad; it is then that the weather becomes fine, bright and warm, and the days long, so that he can be constantly out of doors with advantage; it is then that all nature awakes with renewed life, and the earth, the hills and mountains become clothed with new beauties, imparting endless pleasure to the invalid in his walks and excursions."

It is also advised that the health seeker should not return directly home, but should spend not less than a month on the way, among Swiss resorts for example.

There are certain circumstances that must not be forgotten by the invalid at the Riviera, if he is to derive full benefit from his residence there. The temperature in the sun and that in the shade differ very considerably. The temperature in a room exposed to the north is during the day several degrees colder than one with a southern exposure, specially if the direct rays of the sun are beating upon the latter. For while the shade temperature during the winter months is 55°·9, that in the sun may be as high as 128°·9 Fahrenheit. Invalids may require then to take the precaution of having a room with a southern exposure in winter. Then with the setting of the sun the earth speedily begins to cool, and there is a sudden change in the temperature, and the nights are sometimes very cold. Exposure at night must, therefore, be avoided, the invalid systematically returning home sometime before sunset. In view also of sudden alternations of temperature during the day precautions should be taken. "Invalids should be warmly clad, wearing in fact very much the same winter clothes they would do if in England, the object being to keep themselves as far as possible comfortably warm, even to the hands and feet. It is very advisable that they should carry with them, when out of doors, an extra coat or shawl, which even in the house it is often requisite to wear. The San Remese, and indeed it may be said Italians on this coast generally, very commonly carry a second coat, in readiness to put on, should the weather become suddenly chilly; and it is by no means uncommon to see men wrapped up in shawls, much in the same way as women. It is impossible to be too careful in this respect." "Invalids, especially if suffering from chest affection, should not go out when the air is damp, when it rains, or when strong cold or damp winds are blowing. They should be most careful about sitting out of doors; they must only do so when the sun is shining and they are themselves placed in some warm and sheltered situation. If a suitable locality be chosen they can often bask in the sunshine during the winter for hours together. It is advisable always to be provided with a sunshade, as, if the powerful rays of the sun are allowed to fall directly on the head, they frequently give rise to troublesome headaches of a congestive character. Over-fatigue should be scrupulously avoided; no long excursions undertaken, and above all, if the lungs be affected, climbing up the hills and mountains should be absolutely forbidden. Much mischief occasionally ensues from a neglect of these precautions."

We conclude these considerations of the general features of this district, by noting what is the kind of disease for which the climate is most suitable. It is eminently suited for that class of invalids, who, without actual organic disease, are yet broken down in health from overwork or strain. The dryness which accompanies its warmth, as well as the effect of the sea air and the bright sunshine, make it tonic bracing and stimulating, just such qualities as are desired in the class of cases named. Digestion is improved; and the processes of tissue change and repair are quickened. The skin and circulation are also stimulated. Those same qualities indicate the benefits likely to be derived by those recovering from acute disease, by the aged and those too rapidly aging. Delicate children are also suitable patients, especially those constitutionally so, from scrofula or similar

diseases of bad nutrition. Lung affections, of the consumptive kind, or of the bronchial variety, *if not acute*, are likely to improve with a sufficiently prolonged residence. But for some such cases the climate may be too bracing, for others, and this is more likely, it may not be sufficiently so. Each patient's own particular condition must be the indication of its suitability or otherwise. Consumption with a tendency to inflammatory action is deemed unsuited for treatment here, while the air is not sufficiently moist for nervous asthma. Digestive troubles, and disorders of the urinary and sexual organs may be aided in removal by the Riviera climate, but there are other much more suitable places, in which climatic treatment is combined with treatment by baths and mineral waters. It is not recommended in cases of heart disease nor for persons of a full habit of body, nor for those suffering from diseases of the nervous system.

We shall now note a few of the leading features of the chief resorts already discussed in their general features, noting any differences existing between them.

San Remo, situated on the Gulf of Genoa, is the typical place of the Riviera. Sixteen miles to the westwards is Mentone, 15 miles farther west is Nice, and Genoa is 85 miles farther east. It lies in a bay four miles broad, and is protected by an amphitheatre of mountain, rising gradually behind it from a height of 500 to nearly 4000 feet, the nearer ones being wooded with firs. East and west the promontories of the bay shelter it, and, unlike Mentone, it has within the circle of its hills no gorge or valley down which the north wind may sweep. It is more protected from the mistral than Cannes or towns farther to the west. The town contains 16,000 inhabitants. Corsica lies 80 miles to the south-east. The western part of the town stands on a higher elevation than the eastern and is nearer the sea, being consequently more bracing. Groves of olives shelter its lower levels. It is warmer than Nice or Cannes, though its annual temperature is slightly lower than that of Mentone, from which latter, however, it does not materially differ; while its rainy days, as shown on p. 790, are fewer. "Its climate," says Dr. Rose, "is intermediate between the east and west ends of Mentone, not so warm as the former and more sheltered than the latter, the air being also more soothing than at Cannes, Nice, and Mentone. This depends on the fact that the ground is covered to the water's edge with orange, lemon, and olive trees, thus preventing too rapid evaporation, and the soil, being principally clay, prevents the rain percolating through so rapidly as it would in sandy and gravelly soil." It has been noted that this soothing character of the San Remo air is in contrast with the more stimulating effects of the atmosphere of Nice, as shown by a tendency of the latter to produce sleeplessness, whereas in San Remo the air did not have this effect, "being tonic without being excitant, exhilarating and yet soothing." There is plenty of variety for walks and excursions, and the invalid who cannot venture far may exercise, sheltered by the orange groves.

Mentone, a town of 5000 inhabitants, is situated in the centre of a bay, about 4 miles wide, which is divided into an eastern and western portion by a projecting spur. The eastern portion is completely protected by the mountains which rise abruptly without break, and shelter it from the north, north-east, and north-west, while it is open to the south and south-east. The mountains behind the western portion are farther removed and are interrupted by valleys, through which the wind sometimes rushes with violence, and through which the mistral may find entrance, though modified by the mountains. The eastern bay is thus warmer than the western, but is rather restricted for exercise, while the western bay has plenty of space for exercise in parts well sheltered for the invalid. The difference of temperature between the two bays is so marked, that invalids residing in the eastern bay are advised not to pass the limits of that bay in the cold days of winter. Its mean winter temperature is between 48°·5 and 49°·5. The climate of Mentone "is warm, very dry, and stimulating; it is also very equable, being much less liable to sudden changes of temperature than Nice or Cannes. There is a want of circulation in the atmosphere, particularly in the eastern bay; and a close proximity of most of the houses to the sea subjects patients too much to the noise and stimulating effects of that element." But it is these qualities of the eastern bay that make it very suitable for some kinds of consumptive patients.

Monaco lies between Nice and Mentone, 10 miles from the former and 5 from the latter, on an elevated promontory. Just beyond it is the Casino of Monte Carlo. The lower town of Monaco is well protected on its westward side.

Nice is a town of over 40,000 inhabitants. It is not nearly so well protected by the Alps as any of the towns already named, because of its

distance from them and their lower elevation. Of it Dr. Hassall says: "It is insufficiently protected by its beautiful encircling mountains, especially from the north-east and north-west winds; when these blow, the city is liable to sudden and great changes of temperature; changes which are somewhat dangerous even to those in health, and positively injurious to persons suffering from lung disease. Were Nice better protected from objectionable winds, the climate would be nearly equal to that of the most favoured of the health resorts of the Western Riviera. Like that of the Riviera generally, it is, even in winter, bright sunny dry and stimulating. The average annual temperature is 59°·48, and the three months' winter temperature 47°·82; it is, therefore, colder than either San Remo or Mentone; the rainfall amounts to 25 inches, and the number of rainy days according to De Valcourt to 70, being greater than all the other towns of the Riviera, with the exception of Mentone. Although, therefore, the climate of Nice is at times trying and treacherous, and hence unsuited to most invalids, there are yet some who derive benefit from its stimulating and bracing qualities; as those suffering from simple debility, atonic dyspepsia, and scrofulous affections. For some aged people it also affords a good winter retreat, provided they are on their guard and conform to the exigencies of the climate." And Dr. Walshe says that in no stage, in no degree, and in no form of tuberculization of the lungs, and no matter what be the temperament of the patient, is Nice proper a safe winter resort.

Cannes, strictly speaking, is beyond the limits of the Western Riviera. It is a town of about 14,000 inhabitants, situated on the Bay of Napoule, on its eastern side. Nice lies 19 miles to the east of it. It is sheltered on the west by the Esterel Mountains, while Cape Croisette protects it on the east, and on the north, north-east and north-west, it is sheltered by slopes of the Maritime Alps. They are, however, too distant and too low to make the shelter complete, and the north-west wind—the mistral—is a greater plague at Cannes than at the other chief towns of the Riviera. A thick yellow dust frequently covers the roads, and is lifted and driven in clouds by the wind. The old town is built on a ridge, Mont Chevalier, 147 feet high, which divides the bay into an eastern and western portion; the former is the smaller of the two and is more sheltered from the mistral. Its climate is dry, bracing, and stimulating, with a mean winter temperature—48° Fahr.—somewhat lower than San Remo or Mentone, while it largely exceeds these in the number of its rainy days (see p. 790) and the amount of its rainfall—25 inches. It is, therefore, not so well suited for those suffering from chest complaints. It has, however, advantages of its own in its less confined area, in the variety and beauty of its surroundings, and its absence of closeness. On the slope of the mountains, about 1000 feet high, and distant from Cannes 8 or 9 miles, is **Grasse**, with a southern exposure and fairly well sheltered, and famous for scent manufactories and for preserved and crystallized fruits; while north-east is the village of **Cannet**, famous for pottery-ware, whose air is more soothing in its influence than that of Cannes. Opposite Cannes, about a mile from the shore, are the islands of St. Marguerite and St. Honorat. Thus the surroundings of Cannes are varied and beautiful, and it affords a great variety of walks and excursions, a not unimportant matter in considering what is to be the winter residence of invalids.

Hyères lies still further west than Cannes. It is built on the slope of a range of hills, 60 feet above the sea-level, and is protected from north and north-east, but is open to the north-west wind. Its exposure is southern, and it is 3 miles inland. Its mean winter temperature is 47°·3; its average annual rainfall is 27 inches; and its number of rainy days 63. "The climate of Hyères is very good between November and the beginning of February, with many calm and sunny days; it ought to be avoided after this period by those who are unable to bear the mistral, or at all events the greatest care ought to be exercised. In April and May Hyères offers again more advantages. Many cases complicated with nervous irritability do much better here, because it is less under the direct influence of the sea than Nice and Mentone" (Weber). This lessened stimulating effect of the climate of Hyères, as compared with that of Cannes, Mentone, or Nice, is shown by the fact that patients driven from the latter towns by sleeplessness have slept soundly at Hyères.

Genoa lies at the eastern end of the Western Riviera. Its mean temperature is 46°·56, considerably lower than the more westerly towns, with more days of rain, more frequent visitation of frost, and above all with an exposure to the north and north-east. It cannot be counted, therefore, as a winter health resort for the invalid, nor is it suitable as a brief place of

residence after a winter in milder climates. For those not strictly speaking invalid it has of course manifold attractions; and if its climate is not mild in comparison with San Remo it is yet bright and sunny.

Malaga, in Granada, on the south coast of Spain, 80 miles east of Gibraltar, is protected from the north and north-east by a range of mountains rising to a height of 3000 feet. It is, however, exposed to the north-west wind. Its winter temperature compares very favourably with those Mediterranean health resorts already named, being 54° to 55°, while that of San Remo is 48°·89, and its spring temperature 62°, while in San Remo it is 57°·32. The daily range of temperature is only 5°, the mean of that of San Remo being 9°·22. The air is drier than in the localities further east, and the number of rainy days is only 40, 8 less than at San Remo. February is the rainiest month. Its climate, which has been said to be the mildest climate in Europe, is warm, dry, equable, and bracing, but its exposure to the north-west wind, called here Terral, and which pours through gaps in the mountain chain and is laden with fine sand, is a bad feature. Invalids need to guard against the sudden fall of temperature after sunset, and the heavy dews. It is a suitable climate in the early stage of consumption, in chronic bronchitis with much expectoration, in bronchial asthma, and for children suffering from scrofulous affections. It is not advised for persons with nervous affections, or who are liable to apoplexy, or who suffer from neuralgia or chronic rheumatism.

Ajaccio, in Corsica, faces south-west, being sheltered from northerly winds. Its mean temperature in winter is about 54°, in spring 59°. The air is, however, moist, 80 per cent of saturation, and during the winter and spring the rainy days number 35.

Other Continental Resorts.

Pau is inland, situated in the south-west of France, in the department of the Basses-Pyrénées, 56 miles east-south-east of Bayonne. In a valley and surrounded by the mountains, its sheltered situation produces a very calm atmosphere. This renders it somewhat relaxing. Its mean temperature during the season—November to April—is about 48°·6, and the air is less dry, there are more rainy days—119—and a greater rainfall—43 in.—than in some of the chief places of the Riviera. The soothing influence of its climate is suitable in irritable conditions of the throat and air-passages, and in irritable conditions of the nervous system, and spasmodic asthma. Thus in chronic bronchitis with dry, worrying cough, it exerts a sedative effect. Rheumatism is said to be a common complaint among the native population. Occasional storms disturb the atmosphere, and in the later months of spring the weather is somewhat unsettled.

Biarritz lies on the coast of France within a few miles of the Spanish frontier, in the same department as Pau. It fronts the Atlantic and is quite unsheltered. It has therefore the characteristics of the most of seaside resorts open to the west. Its air is rather moist, and rain is apt to be frequent. But it has a dry soil. It is bracing; and is frequently resorted to in summer, but is suitable also in autumn and spring for those who seek a change without being actually invalids. "Persons disposed to hypochondriasis and mental depression, and many old Indians with their somewhat complicated cachexia, without organic disease, derive great benefit from the cheering influences of this climate, which is also a very good change from Pau and Arcachon." It is not, however, suited for cases of nervous irritability or a tendency to hysteria.

Arcachon, also on the west coast of France, is inland 9 miles. It is protected from the west and south-west, and also from the east and south-east, by the dense pine forest in which it lies. A large basin of sea-water, connected by means of a narrow channel with the Atlantic, diminishes the coldness and dryness of the north and north-east winds which reach it. Its mean annual temperature is 58°, and its moisture 15° short of saturation, its rainfall being 32 inches and rainy days 103. The soil is sandy and dry. "The climate is mild and soothing, and is specially suitable to cases of irritable bronchial or laryngeal catarrh, to cases of phthisis with tendency to congestion or inflammatory complications, and to persons of nervous temperament." To persons of a relaxed habit of body it is not to be recommended. The season is from October to May.

The coasts of Norway, Sweden, and Denmark, the coasts of Holland, Belgium, and Germany, and the shores of the Baltic, are all rich in seaside summer resorts, the features of which are a highly bracing, stimulating, and tonic climate, sea-bathing, and more or less natural beauties.

Alpine climates have of recent years become exceedingly popular especially for the treatment of lung affections. The atmospheric conditions

in elevated situations have been already to some extent indicated in the early paragraphs of this section. The air is very pure, free to a very large, if not absolute, extent, of germ life, or if germ life is not absent the conditions are not favourable to its growth. This is a matter of very great moment in lung affections of a consumptive kind. Then the air is rarefied, because of the lower pressure; it is believed to be relatively drier; it is also colder, the degree of cold being dependent upon the elevation, but the heat of the sun is more intense. The effects of these conditions are experienced mainly by the heart, lungs, and skin. The action of the heart is increased, at first both in force and frequency, but latterly, as the person becomes accustomed to the elevation, the increased frequency disappears. The action of the lungs is also stimulated. The depth of breathing is increased, probably to compensate for the diminished amount of oxygen in the air, and the lungs are thus more fully expanded; the quantity of water and carbonic acid gas given out is increased. The digestion and appetite are improved; and on the skin a bracing and tonic effect is produced. Though the atmosphere is cold the tendency to take cold is lessened, perhaps because of the bracing effect of the cold on the skin, probably also because of the purity and relative dryness of the atmosphere. The whole effect is exhilarating, stimulating to improved general nutrition, which ought to be evidenced by gain of weight, increased elasticity of body and of muscular power. Perhaps the increased quantity of ozone in mountain air is a cause of the marked mental exhilaration. To the same cause has been attributed the sleeplessness which affects the majority of people at great elevations. The sleep is usually restless and filled with dreams for several nights after arrival. This, it is said, passes off at most in a week or two. But it has also been observed that less sleep seemed required, that a shorter than customary period seemed to suffice. On some people, however, mountain air has an effect conducive to sound sleep.

Mountain climates are eminently suited for conditions of depression due to mental or physical overstrain, with weak digestion, depressed nervous system, &c. For those recovering from acute disease, it is also advised as an active agent in quickening the process, and for those whose constitutions have been undermined by malaria, or by a residence in a hot climate, such as India. Chronic bronchitis with excessive expectoration may be expected to benefit, as well as cases of pure asthma, nervous asthma, particularly in the young or those not beyond the prime of life. Chronic catarrh of the throat and air-passages also yields to the bracing tonic influence of the mountain air, and relaxed conditions of the skin with excessive perspiration. The value of mountain climates for consumptive patients has of recent years been much discussed. Dr. Hermann Weber thus expresses his views:—"We cannot, therefore, hesitate to say that in a great many cases of phthisis and phthisical tendency, long residence in certain mountain climates is useful. Prominent among these conditions are: 1, tendency to phthisis, inherited or otherwise; 2, chronic catarrhal affections of the apex, or upper portion, of one or both lungs, without or with affection of the lung-tissue itself; 3, chronic bronchial catarrh of the lower lobes, with much secretion in young people, or, at all events, not in old people; 4, remains of pneumonia (inflammation of the lung); 5, remains of pleuritic affections, with and without exudation; 6, so-called caseous deposits, resulting from catarrhal, pneumonic, or pleuritic affections; 7, the early stages of phthisis in one or both lungs." "*We must add that phthisis, even in the earliest stages, ought to be excluded from European Alpine climates, when it occurs in persons with an irritable heart and circulation, with a constantly rapid pulse, whom the slightest derangement makes feverish, who are unable to bear cold and the slightest changes of temperature. . . . Further, patients with advanced and still progressive phthisis ought to avoid Alpine climates. It may be difficult to promise them a cure anywhere, but at the warmer health resorts of the Rivieras, Algiers, or Madeira, they have more comfort; while others, if they knew their condition, would prefer the sheltered localities near their own homes and friends. The same ought to be said to all those whose condition, if they were to go to the Alps, would be likely to keep them, during weeks and months together, indoors.*"

We have put these sentences in *italics* because many people cannot understand how a climate which has, without doubt, proved valuable in some cases of consumption, should not prove valuable to all, and because they emphasize the fact that it is in the early or only threatened stage of consumption that the climatic treatment ought to be resorted to. Many people when told they ought to leave business, professional duties, or household cares, for a change of air and scene, reply with the query, "Am I so bad as that?" Now it ought not to

be when the patient has reached a grave stage in the course of a disease that he is ordered away, but more urgently as soon as risk seems to threaten, in order to prevent the arrival of a serious change. To the entreaty of the doctor, how often does the patient answer in effect, that he really cannot leave his work at present, that he will wait for a season, that there are no urgent symptoms, and that if urgent symptoms do show themselves, he will then be prepared to sacrifice everything and go off. It is, therefore, necessary to insist that the beneficial effects of all climatic treatment, most certainly in consumptive affections, and specially treatment by mountain air, are obtained chiefly in those periods when the disease is inactive, either before it has actually broken out, or when it seems to be quieting down after an outburst, one might almost say obtained *only* then.

The cases *not suitable* for mountain climates are those of heart disease, aneurism, tendency to apoplexy, dilatation of the lungs (emphysema, p. 283), tubercular disease of the larynx or bowel, tendency to acute rheumatism, or to acute inflammation of the throat and tonsils, convalescence from dysentery, Bright's disease of the kidneys, and the forms of consumption already indicated. Patients with irritability of the nervous system, as well as those who, from whatever cause, general debility, &c., cannot bear the sudden change from the heat of the direct rays of the sun during the day to the cold frosty air of the night, or who need protection from the wind, should not try mountain resorts. The old and the very young come into the last class. We shall now briefly note four of the chief Alpine health resorts; the mountain health resorts of America and India are illustrated under their respective headings.

Davos Platz is the chief mountain resort in Europe for consumptives. Attention was directed to it in 1867 by Dr. Weber, since which time it has achieved a great reputation. It is situated in the Canton Grisons, Switzerland, at an elevation of 5140 feet above the sea. Upwards of 1300 invalids winter there. It may be reached on the evening of the third day from London, the journey passing by Brussels, Basle, Zurich, and Ragatz, the distance from Ragatz to Davos being accomplished by diligence. It lies in a valley 4 miles long, running parallel to the Engadine but in an opposite direction. It is sheltered during the winter, and its atmosphere is still and cold.

The winter season lasts from the middle of October to the end of March. The snow falls early in November and lies crisp and clear till April, when it begins to melt, at which time visitors leave, though a mountain retreat is in summer as beneficial as in winter, for those who can bear the more changeable character of spring weather.

During the day patients go out into the sunshine; the treatment being essentially a pure air treatment, the more lengthened the outdoor life the better. From 10 a.m. to 4 p.m. the warm sunshine lasts; after the latter hour patients return indoors where a constant temperature of 65° is maintained. The temperature outside may fall to 10°, 20°, or more below freezing. This is not felt unduly, because of the purity, crispness, and comparative dryness of the air. From the Platz there is an ascent through pine-woods to the summit of a mountain 1000 feet higher, and this affords admirable exercise in easy stages for those who can attempt it wholly or partly. There is also abundance of amusement in the shape of concerts, &c., during the season. What has been said as to the cases for which mountain air is suitable is fully applicable to Davos Platz.

St. Moritz, another Swiss resort, is in the Upper Engadine, 5710 feet above the sea-level. There is more wind here than at Davos, and it is consequently less suited for those very sensitive to movement of the air. Its temperature is rather lower than that of Davos, but, with the exception noted, it is suitable for similar cases. It possesses an iron spring, and bathing and drinking houses. Its scenery is magnificent, and it affords greater scope for excursions. In winter there is the additional attraction of skating on the lake of St. Moritz. These circumstances, with the presence of the mineral spring, make it more advisable than Davos for those who do not require the more complete protection against wind offered by the latter. Business and professional men, the patient suffering from dyspepsia, sluggish liver, depressed nervous system, &c., will find it exceedingly attractive and bracing.

Tarasp, in the Lower Engadine, may be reached in one day from Davos or St. Moritz. Its altitude is barely 4000 feet. Eight hundred feet above it, reached by a winding path, is the village of **Vulpera**. It is a summer resort, the season being from June to the end of August. It is possessed of a Spa resembling that of the Carlsbad Sprüdel, the waters of which are drunk between 6 and 8 a.m., three tumblers being the rule, with an interval of twenty

minutes' brisk walking exercise between each. It is not advised for consumptive patients, but for the dyspeptic, the victim of nervous depression and a slow liver, and the gouty.

Meran, in the Tyrol, may be reached from Tarasp in a journey by diligence of seventeen hours. It is well protected from the wind, lying sheltered in the Funster valley; and its winter climate is very equable. Its season begins in September. Consumptives resort to it for the "grape cure," which consists in consuming before breakfast three or four pounds of grapes. The patients, who employ the grapes, as others do waters elsewhere, for their action on the bowels, come out in the early morning (about 7·30) and slowly eat the grapes while quiet exercise is indulged in. A light breakfast follows. Consumptive patients are recommended to take the grapes after breakfast up till noon, and to eat them slowly, a pound being consumed. In this way they do not act upon the bowels as in the former.

Atlantic Islands Resorts.

Madeira is the type of warm and moist marine climates. The islands are situated in the North Atlantic, off the north-west coast of Africa, between 32° and 34° north latitude and 16° and 17° west longitude. Owing to the exceedingly equable character of the climate, Madeira was for a long time the chief resort of consumptives, but the moisture of the atmosphere has made it questionable whether it is really suitable for such cases. The chief place is Funchal. Its mean annual temperature is about 65°, the mean winter temperature being 61°, spring 62°, summer 69°·5, and autumn 67°. The lowest temperature is seldom below 48°, and the highest rarely above 86°, the range between day and night being about 9°. The degree of moisture is variable, between 70° and 74°, and the number of rainy days is 74. "Its rainfall in March is sometimes considerable, but from October to May you can always count upon an equable temperature, and weather at least as fine as a favourable June in England, and scenery which is among the most varied and attractive in the world." There are the daily sea and land breezes. The character of the climate is soothing and even relaxing. It is thus specially suitable for irritable conditions of the mucous membrane of the larynx and bronchial tubes, for chronic bronchitis with irritable cough and little expectoration, and for dilatation of the lungs. In early cases of consumption, in persons with excitable circulation, it deserves a trial.

The Canary Islands lie four degrees south of Madeira. The principal island is Teneriffe, extending 60 miles from north-east to south-west, 60 miles across at its widest part, and less than 16 miles at its narrowest, famous by its peak, which rises 12,000 feet above the sea-level. The capital is **Santa Cruz**, a town of 15,000 inhabitants, but its chief health resort is **Orotava** on the north-western side, reached from Santa Cruz by carriage in a few hours' drive. The town lies about 3 miles from the sea-coast and fully 1000 feet above its level, but the town of Port Orotava lies on a peninsula bathed by the Atlantic. The latter has become the most popular resort of recent years; and the following notes of the character of its climate are derived from letters written to the *British Medical Journal*, by the editor Mr. Ernest Hart, in 1887. The town lies on the brow of a hill, and behind it rise the mountain slopes of La Cumbra, "rising like scarped bastions to a height of 8000 feet."

The mean temperature of the year is 68°·5; between the hottest and the coldest month the temperature does not vary more than 14°, while in London it amounts to 26°·1, in Pau to 35°·8, in Madeira to 14°·9, in Algiers to 23°·5. The winter temperature is 63°·8, that of London is 41°·7, of Nice 49°·6, of Algiers 58°·3, of Madeira, 61°·7. "Moreover, it is not a mere lessening of the temperature, but quite another world. Neither at Nice, at Rome, at Naples, nor anywhere in France or Italy, can you dispense in the winter with fires at given periods of the day. I have felt it colder in going out after sunset along the Promenade des Anglais at Nice than almost anywhere else. I have shivered in a greatcoat in crossing the Libyan Desert in March, and twice I have passed through heavy hail-storms. On a dahabieh on the Nile ice will form on deck sometimes at night, so great is the fall of temperature after sunset. At Orotava, as Belcastel picturesquely puts it, a chimney would be ashamed of its perpetual nudity. There are none. Throughout the winter you bathe in the sea at Port Orotava, with as much pleasure as at Brighton in July." The extreme range of temperature during any one day during the six winter months does not exceed 5°·4, whereas even at Madeira it amounts to about 12°. "Orotava is not less remarkably favoured in respect to the singular dryness of the air, which makes it peculiarly valuable for a large class of invalids suffering from chest and throat affections, and in this respect it has an enormous

advantage over Madeira. The rainfall at Madeira is estimated at 29 inches, that of Teneriffe amounts on the average to 14·7 inches, so that Orotava is twice as dry." The average relative humidity of the air varies from 53 in December to 79 in August. The refreshing land and sea breezes play with perfect regularity, the Peak of Teneriffe cutting off the north-east wind or brisa. "In short all the conditions present make the climate an ideal one both for lovers of health and lovers of Nature. Orotava has the exceptional advantage of being quite free from mosquitoes, which cannot be said of Las Palmas and Santa Cruz. In the Canaries generally there are no poisonous snakes or venomous reptiles." "From one year's end to the other the variation of temperature does not exceed 18°, and this within the limits which are most favourable to life. That is the whole magic of this climate. There is no excessive heat in summer; no cold in winter. Very small rainfall, and that chiefly at night. No chill at sunset; no heavy dews; no frosts; no sirocco. It is a climate full of geniality with neither bite nor burn. A garden of flowers which bloom perennially. It has the charm of temperate zones, without their fluctuations and their drawbacks; the delights of southern continents without their pests, such as mosquitoes, venomous beasts, and insects, their excessive heats, their miasms, or their heavy rainfall." "Medically Teneriffe is of course peculiarly suited to that important and numerous class of invalids who suffer from affections of the lungs and of the air passages," from consumption in various stages, Bright's disease and diabetes. Of it Professor Jaccoud says, "The climate of Teneriffe is drier and more tonic than that of Madeira, and it is capable of completing and usefully extending the therapeutic applications proper to Madeira in a number of cases. It unites the advantage of mild and equable temperature with those of proximity to the sea, and with the advantages of mountain climates." For in summer one may betake one's self inland and up the mountain slopes to the town of Orotava already mentioned, where the temperatures are slightly lower in winter, and perceptibly so in summer, but equally mild and equable. **Laguna**, on the road from Santa Cruz to Orotava, "offers a summer climate which leaves nothing to be desired," and affords to those who need it a more bracing air. "There are the capabilities of a high mountain station which would rival Davos, but they are not yet developed by suitable residences for invalids. Thus Teneriffe seems to possess all the resources which could be desired for residents throughout the year. Its capabilities as a summer resort still await further development, and I believe that it is intended to arrange hotel accommodation near La Paz, at Icod, and at Laguna, which will be a great boon to those who desire to spend the summer months in Teneriffe. Meantime there is no small number of houses to be had which were built by the vine-holders and cochineal-planters in the days when these agricultural industries were a source of great wealth, which they have now ceased to be. These houses, built in the Spanish style and suitable to the climate, may be rented at present (1887) at very low rates. I heard of rents of furnished villas varying from £2 a month up to £10 a month, the latter being the rent of a beautiful villa with a delightful garden. The wages of servants are very low indeed, and their diet is most frugal; so that, at the present scale of prices, permanent residence in Orotava is as cheap as it is delightful and healthful. I cannot but think that it is destined to become the most favoured health resort for Englishmen, and indeed for Europeans generally." It may finally be noted that difficulties which existed in getting to Orotava have now disappeared; that the passage may be made from Liverpool to Teneriffe and back by African lines of steamers for the sum of £15, which includes maintenance on board steamer on the most liberal scale for the eight days' journey out and the eight days' journey back; and at Orotava there is now excellent hotel accommodation.

It may be that, as indeed has been said, Mr. Ernest Hart has presented too roseate a view of the delights of the climate of Orotava. At any rate it has a rival in its immediate neighbourhood, namely Las Palmas.

Las Palmas is a town having a population of 12,572, situated on the Grand Canary, an island nearly circular in shape, of a diameter of 24 miles. It faces the Atlantic on the east, and behind it the island rises abruptly to a height of 250 to 300 feet, stretching out as a dry barren plain for about 2 miles. The nearest point of the African coast is distant 120 miles. It is said to be more interesting than Teneriffe, and for visitors it possesses the advantage of a fine sandy beach, 4 miles long, with abundant opportunities for bathing. The mean temperature of the six coldest months, November to May, is 63°·10, the mean of the highest is 68°·53, the mean of the lowest 57°·27, and the mean daily range 10°·86. The moisture

of the atmosphere ranges from 54 to 70 per cent of saturation, and the annual rainfall amounts to 14 inches. "Las Palmas is favoured with a large amount of sunshine. The sun glows with great brilliancy, and pours down its life-giving rays through a sky of the most beautiful azure, making the air so luminous that everything looks bright and cheerful. Indeed all nature seems to rejoice in the sunny glory of Grand Canary, the most favoured of the 'Fortunate Islands.' The clear, pure, moderately dry air with which the 'gentle' trade-wind fans Las Palmas is very refreshing and invigorating." In summer the mountains offer a beautiful retreat from any undue heat. The climate is suited for consumptive cases, for chronic bronchitis, for diseases of the kidneys, for chronic rheumatism, and indeed for such cases as Orotava is suited for. "Although the daily range of temperature is slightly more than Madeira, this is more than compensated for by the tonic properties of the air, which is drier and bracing and illuminated by more brilliant sunshine. Las Palmas obviously possesses important climatic advantages over all of the famous health resorts of the south of Europe or the north of Africa. The invalid may be out in the open air all day long, and may sleep with his bed-room window wide open. Very rarely will he have occasion to remain indoors on account of rain." So writes Dr. Mordey Douglas, of Sunderland, who goes on to add, "During the seven months I was there I was only once prevented going out by rain. . . . Personally I have the greatest reason to be thankful that I sought the restorative influences of this splendid climate. I went branded with the ominous words 'no hope,' and have returned, as you see, a new man, with my health immensely improved. On the good opinion I formed of the climate of Las Palmas I did not hesitate to stake my life, and will do so again if necessary. And why should I hesitate, when after the most rigid and careful consideration I am forced to the conclusion that Las Palmas has the finest climate in the world of which we have any knowledge."

The Azores in Mid-Atlantic have a climate similar to Madeira.

African Health Resorts.

Algiers on the north coast of Africa has a climate of the general character of the districts on the Mediterranean shores, which sea is the chief influence in determining its exact nature. The mean temperature of the winter season, which extends from the end of October to the end of April, ranges between 57° and 62° Fahr., the daily range being about 12°, and during the same period the rainy days number between 45 and 65. It is exposed to the north-west wind, and suffers occasionally from the sirocco, hot and laden with sand from the desert, from which, however, the mountains afford considerable protection. The atmosphere is moderately humid. In early stages of consumption the climate is beneficial and in recovery from inflammation of the lungs. Bilious subjects do not benefit, nor is it suitable in Bright's disease. Sixty miles south-west of Algiers, 15 miles inland, and situated among the hills in the neighbourhood of pine-woods, are the hot springs of **Hammam R'Hira.** Here the air is drier and more stimulating, and moderately warm. October, November, and December are the best months, as towards the end of December, and in January, February, and March, it is rainy. Fair weather is again experienced in April and May. It is specially suitable for rheumatic and gouty patients. Hot saline baths are to be had and an iron spring for drinking.

Tangiers offers a delightful climate of the humid class, but mild and bright.

Egypt offers the most notable illustrations of a dry climate with heat. The air is dried by the desert, and owing to its clearness and freedom from moisture no screen is interposed to the rays from the sun. At sunset, however, radiation from the earth takes place rapidly and the nights are, consequently, very cold, with heavy dews. Thus while the mean temperature in December is 58°·5, the highest is 75° and the lowest 39°, showing an average range of temperature of 36°. The mean temperature for the four months December to March is 59°, and the mean daily range 40°. During these months the moisture of the atmosphere, as compared with June, July, and August in England, is as 56 to 81. Thus the marked feature of the climate is the dryness and clearness of the atmosphere, rain being practically unknown during the season. One notable effect of such a climate is its markedly stimulating action on the skin, the result of which is relief to deeper organs and specially the kidneys. In Bright's disease this climate offers benefits such as almost no other climate does; also in chronic rheumatism and gout and chronic catarrhal complaints, chronic bronchitis with excessive secretion. In early phthisis or in cases of consumption at other stages, but not active, the dry air of the desert

is beneficial, and may arrest the progress of the disease.

Alexandria owing to its proximity to the sea has a moist atmosphere, which renders its climate uncomfortably hot, even when the temperature is not above 70° or 75°. **Cairo** is an improvement in this respect, but **Heluan,** 14 or 15 miles south of Cairo, Luxor, Assouan, and the Nubian Desert are the chief localities. Cairo has, of course, all the advantages of a town, and all its disadvantages of polluted atmosphere and insanitary conditions also. Heluan boasts a hotel and bath-house, and, in the desert, tent life is the rule. The Egyptian season begins with November and lasts till March, later than which the invalid must not stay. The return home should not be direct, but might be by the Grand Canary or Teneriffe, the higher stations being chosen for a brief residence.

South Africa possesses many health resorts, mountain as well as by the sea. Of the latter are **Capetown, Port-Elizabeth,** and **Port Natal. Capetown** has a mean winter temperature of 57°, spring and autumn 64°, summer 71°. Its characteristics are moderate dryness and warmth and the stimulating effect common to most coast places. Wind and dust are the drawbacks. In the interior the atmosphere is very dry.

In the interior **Bloemfontein** is the best-known place, being situated 4700 feet above sea-level, but **Pretoria, Heidelberg,** and many other places in the Transvaal are held in repute. The long journey by ox-wagon is the great objection to seeking these localities.

American Health Resorts.

It is not our object to do more than indicate a few of the leading features of some of the principal resorts in America recommended in recent years, and specially for those suffering from diseases of the lungs of a consumptive kind.

San Diego lies on the sea-board of California, fully 500 miles south of San Francisco, and just about the border of Lower California. It lies on a slope facing a bay, the bay of San Diego. The slope extends inland about a mile, gradually rising to a height of 200 feet, and is succeeded by a rolling table-land stretching for miles inland. The bay is formed into a natural harbour by a peninsula that stretches out a long protecting arm between it and the Pacific, the arm spreading out at its termination to an area on which is built the city of Coronado. At the end of 1887 the population of San Diego was 25,000; two years before it was not more than 4000. The people seem to be fully alive to the possible future of their city, and provision for effective drainage and water-supply has already been made.

As to the climate of San Diego, its mean summer temperature is 66°·7, the mean highest summer temperature is 88°·6, the mean of the lowest winter temperatures is 54°·4, the mean annual temperature being 60°·5. The relative humidity of the atmosphere is 72·9 per cent of saturation. Between the mean day temperature and that of the night in the month of January for twelve years the difference was only 13°, and the difference between the day and night temperatures for July was only 9°. The winter temperature never falls below 32°, and in ten years reached that point twice only. The atmosphere is rarely burdened with fogs, and blizzards are unknown, though hot dry winds from the desert blow occasionally, more frequently in winter. There are daily land and sea breezes, which blow for about three-fourths of the year with unfailing regularity, the remaining time being occupied by rain winds, which come from a southerly or south-westerly direction, and calms. "The great mountain range of California, the Sierra Nevada, practically terminates in San Diego County, while the foot-hills and elevated table-lands are continued into Lower California. The various peaks of Julian, Cuyamaca, Laguna, Palomar, Greyback, San Jacinto, &c., vary from 5000 to over 10,000 feet in height, and unite to make up the picturesque landscapes for which the county is so famous. These mountains are thickly wooded, and throughout the year covered with rich verdure, whose balsamic exudations from pine, hemlock, tamarack, &c., give a special character to the atmosphere. The climate is exceedingly dry and bracing, with an abundance of warm sunlight in winter and refreshing coolness in summer. . . . The highest elevations are seldom visited by invalids, inasmuch as the desired relief is generally obtained by a sojourn at lower levels. . . . During the summer, however, there is nothing so enjoyable as a trip to these mountains; and, as game is everywhere abundant, it is a paradise for hunters and camping parties."

The climate is suited for some classes of consumptives, for those suffering from malaria, for catarrhal conditions of the throat, nose, and air-passages, for asthma and hay-fever, a more or less dry air being obtained as the invalid retreats upwards and inland, or keeps near the coast-line. In summer the consumptive is advised not to remain below an altitude of 2000 feet,

while in winter he may venture as far as the coast. In the valleys and in the elevated back country there are various small towns, such as San Jacinto, Elsinore and Linda Rosa, where hot sulphur bathing is to be had, so that the invalid has a choice of locality for his particular complaint.

San José is the principal town of Santa Clara County, California. It is 50 miles south of San Francisco, and with suburbs numbers 25,000 inhabitants. The western boundary of Santa Clara County lies 20 miles inland from the Pacific coast. "The county consists of a level valley varying in width from 6 to 18 miles, bounded on the north by the county of Alameda and Bay of San Francisco, extending south-easterly a distance of 50 miles and girt on either side by rolling hills and mountain ranges." The highest mountain summit, 4443 feet above sea-level, is Mount Hamilton, which is crowned by the Lick Observatory "with the largest telescope in the world." The mean temperature of this region is about 70° in summer and 55° in winter. In winter the lowest temperature is rarely below 30°, and this lasts only a brief period. "The average annual rainfall for twenty years was 16·17 inches. There is no rain during the summer, and the country after harvest, when the hills are brown and dusty, presents the most unprepossessing appearance." January and February are probably the best months, and in the hottest months of the year the mountains offer a refuge.

The climate, like that of San Diego, is equable and mild, with an atmosphere moderately humid and, therefore, resembling the warm moist climates of the Mediterranean.

Denver, Manitou Springs, and **Colorado Springs** in Colorado among the Rocky Mountains are the chief health resorts, at present, in America for the treatment of consumption.

Denver lies at an altitude of 5200 feet, and in 1880 had a population of over 30,000. Its situation is thus described by Dr. Denison:—"As seen across the plains from the city, the mountains, which residents of Denver and Colorado generally consider their own peculiar heritage, present a magnificent appearance. Apparently only 2 or 3 miles distant—owing to the wonderful clearness of the atmosphere—they are in reality 12 or 15 miles away, and seem to sweep around the city in the segment of a circle, in three tolerably distinct tiers, from Long's Peak, 50 miles north, to Pike's Peak, 80 miles south. The foot-hills, the first tier, rise two or three thousand feet above the plains, seamed with cañons and gorges, or dotted with sunny pastures; the second tier rises still higher, and more indistinct, while above all, the glistening peaks of the snowy range rise 13,000 or 14,000 feet into the intense blue sky."

Manitou Springs, Colorado, lies, at an elevation of 6370 feet, 75 miles south of Denver and 6 miles west of Colorado Springs, in a little valley sheltered on three sides by the hills. Running through the valley is Fountain Creek, upon the banks of which are the springs, six in number, on account of which the place is named. "Long before the medicinal virtues of the springs of this region were known to the white settlers, the Indians of the Rocky Mountain tribes were accustomed to bring hither their sick and afflicted to drink of and bathe in these waters, appropriately applying the name 'Manitou,' or 'Great Spirit,' to an agency of relief they deemed supernatural." These springs with their picturesque surroundings, and tonic atmosphere, yearly attract many invalids to Manitou, which is rapidly gaining favour, both as a summer and winter resort. In his *brochure* upon the mineral waters of this locality, Dr. S. E. Solly remarks: "The Manitou and Navajoe have been highly praised for their relief of old kidney and liver troubles, and the Iron Ute for chronic alcoholism and uterine derangements. Many of the phthisical patients who come to this dry bracing air, in increasing numbers, are also said to have drunk of the waters with evident advantage."

Colorado Springs is 6 miles from Manitou, and its altitude is 6000 feet.

The temperature, relative humidity, and rainfall in inches are shown in the following table:—

	Denver.	Manitou and Colorado Springs.
Mean Spring Temperature...... ..	47°	45°
,, Summer ,, ...	71°	68°
,, Autumn ,, ...	50°	48°
,, Winter ,, ...	29°	28°
,, Annual ,, ...	49°	47°
,, Relative Humidity (p. cent)	46	49
Yearly Mean Rainfall (in inches).	16	15

This table shows that at these resorts there is considerable variation of temperature at different seasons; and there is also a considerable difference between the sun and shade temperatures, and between day and night. This of necessity arises because of the great clearness of the air, permitting the sun's rays to be felt in full force during the day, and the absence of cloud permitting rapid loss of heat with sundown. In summer the neighbouring hills offer

retreats from the excessive heat, camping out in tents being resorted to. The chief feature of the atmosphere is its dryness, and Dr. Denison concludes that *cool dry* climates are better adapted to the needs of consumptive patients than warm climates with moisture, or even warm dry climates, and it is to these features of the atmosphere of the Rocky Mountains that he assigns the curative influence. Asthma, inflammatory cases of consumption, and cases attended by bleeding from the lungs, in the early stage, are those which he believes to be best suited to such high altitudes; while those complicated with heart affection and chronic bronchitis he believes unsuited. Finally he concludes that "a somewhat *prolonged residence* is essential in the climate in which a certain consumptive finds his disease arrested; and a partial recovery generally necessitates a permanent residence, the return to the locality of the origination of the disease, except temporarily, being generally regarded as a dangerous procedure." Those who wish to study Dr. Denison's very full discussion of the subject will find it in his *Rocky Mountain Health Resorts*, published in 1880.

There are other resorts in America of a nature similar to those in Colorado, which cannot be discussed here, **Santa Fé**, 7000 feet above the sea-level, in New Mexico, and in South America among the Andes are similar resorts, such as **Santa Fé de Bogota** (8648 feet), **Quito** (10,000 feet), &c. The former has a remarkably equable temperature, 59° Fahr. in winter, and 59°·5 in spring and summer. Of the South American resorts, Dr. Weber says: "In no other climate have we witnessed such good results on our patients as in the Peruvian Andes; but the distance from home is great, and some invalids find it difficult to accustom themselves to Spanish, or rather Peruvian-Spanish, habits of life." He speaks specially in reference to **Jauja** and **Huancayo**, the health resorts for consumptive patients from Lima in Peru.

Florida as a health resort has come into prominence within the last ten or twelve years. The northern extremity of the state, bordering on Georgia and Alabama and forming the north-eastern shore of the Gulf of Mexico, will naturally differ in climate from the middle division of the state, washed on the east by the Atlantic and on the west by the waters of the Gulf; and this middle division will again vary considerably from the extremity of the peninsula, not only because the latter is nearer the tropics, but also because round it sweeps the warm current of the Gulf-stream. The easterly winds, warm from the Gulf-stream, keep the eastern or Atlantic coast of Florida warmer by more than 1° than the Gulf coast, making the winter climate of the former milder and more equable than the latter. In the northern division the extremes of temperature are 105° and 20°, in the middle division—the Orange Belt—they are 100° and 25°, and in the extreme south 95° and 30°. These, it is to be noted, are *extremes*. In the middle division the climate is characterized by remarkable equability, freedom from sudden change and marked cold, and not subject to excessive heat. Frost sometimes occurs; when it does, great damage is done to orange culture, as in the cold snap of 1886. A remarkable feature of Florida is the enormous number of inland lakes, said to number certainly 1200 fresh-water lakes, the largest of which, Lake Okeechobee, has an area of 1000 square miles, and the smallest less than 100 square feet. Lake Okeechobee is at the northern border of the southern division of Florida, and south of it there extends an enormous tract of marsh, filled with islands, called the Everglades, or in Indian, "Grass Water." These Everglades cover an aggregate area of fully 7500 square miles; the water varies in depth from a few inches to several feet, rarely more than ten. "Tall grass, as high sometimes as 8 or 10 feet, is very common, with shrubs, vines, trees, moss, and all sorts of tangle and roots. Islands lie here and there, with trees and vines on them—cypress, pine, oaks, palmettoes, magnolias, and a score at least of other sub-tropical trees. Fish in infinite variety abound everywhere." The waters are not stagnant and foul, but clear and pure, and said to be even drinkable. In the rainy season, July to October, the Everglades are impassable. In 1881 a company began operations to reclaim by drainage this submerged land in the neighbourhood of Lake Okeechobee, already with considerable success. It is this enormous area of water-covered land, along with a coast-line of nearly 1200 miles, that is the main factor in producing the singularly equable climate.

One of the chief health resorts is **Jacksonville**, on the St. John's River, a few miles from the coast, not far from the northern boundary of the state. Its proximity to the Atlantic confers on it a climate characteristic of that of the mid or semi-tropical division of Florida. Its mean temperature for the year 1887 was 68°·1, the maximum 100°·3, and the minimum 21°·9. The mean winter temperature is said to be 60°, and

the summer 80°, while the mean relative humidity for the five months, from November to March, is 68·8 per cent of saturation.

St. Augustine, on the coast, 36 miles south of Jacksonville, the oldest city in the United States, and "noted for its picturesque beauty," is a favourite resort. **Key West**, on one of the multitudinous islands of the Florida Keys, the whole area of which is 12 square miles, is another of the favoured resorts. Its mean relative humidity for the months November to March is 76·8. On the Gulf coast from **Cedar Keys**, 127 miles south-west across the peninsula from Jacksonville, down southwards past Punta Rassa, on to Monroe County and the Ten Thousand Islands, is a coast-line offering a suitable climate for a winter health resort, though, as already stated, fully a degree lower in temperature than localities of a similar latitude on the Atlantic coast. **Punta Rassa** is 200 miles south of Cedar Keys and 100 north of Cape Sable. Its mean annual temperature is 73°·4. The lowest monthly mean temperature—that of December—is 64°·5, the highest monthly mean temperature—that of July—is 81°·3. Its mean relative humidity for the winter season—November to March—is 72·7 per cent. Along this coast there are numerous harbours, visited by coasting steamers, where accommodation for travellers is now being provided.

The mid division, then, of Florida is the one which offers the chief advantages to the traveller for pleasure and the seeker after health. As a winter climate it is remarkable for warmth, equability, and moderate dryness. The state of Florida is said to be the healthiest in the United States. The U.S. census reports give the deaths from consumption as equal to 58 out of 1000 from all causes, while in New York State the number is 168, in California 138, in Maine 258. As to malaria it is doubtless to be found in the marshes of the Everglades, but not upon the coast.

Florida offers a unique climate for the sufferer from general ill-health, who is still not the victim of any particular disease. Not only does its equable and moderately dry climate offer unusual opportunities for an out-of-door life, but its varied and luxuriant vegetation, the semi-tropical character of its scenery, its inland lakes, its coast-line, the antique aspect of some of its towns, all bring to the utmost that powerfully healthful influence to bear on the depressed spirit and broken-down nervous system, which is summed up in the phrase "change of scene." Sufferers from lung diseases and consumption are also sent there. It is suited to them, *if the disease is not advanced.* If they seek and are capable of an out-of-door life, free from sudden and extreme changes, where they may lead an existence not of chronic invalidism but of active work, it is a suitable climate. But patients ought not to be sent there as a last resort, nor in the desperate hope of arresting a disease already far advanced. The climate of Florida is indeed fitted for such cases as have been described as benefited by the Riviera resorts of the Mediterranean. While we have noted the kind of consumptive cases for which it is beneficial, we remark that it is yet probably excelled for such cases by the drier air of mountain resorts.

The Bahama Islands, or Lucayos, lie to the south-east of Florida, and are washed by the waters of the Gulf-stream. Of the twenty-nine islands New Providence is the most populous, and contains the capital, Nassau. The lowest mean monthly temperature—that of January—is 70°, and the highest—that of July—82°. Equability is therefore a notable feature of the climate. From November to April, the winter season, the climate is most agreeable, and the rainfall is small. The mean relative humidity for the five winter months is 73·2. New Providence was held in repute as a climate for consumptives, but lung affections are common among Africans and the coloured race, and among the black troops, stationed at Nassau, the proportion invalided from this disease was very high. Those for whom Madeira is recommended would probably find the Bahama Islands still better, because of their greater equability of temperature.

Bermudas or Somers Islands, situated in the Atlantic, 600 miles east by south of Cape Hatteras, are another winter resort for America. The mean temperature is 70°, maximum 85°·8, and minimum 49°. They afford, therefore, a warm, equable, marine climate. They have been subject, however, to four attacks of yellow fever in the last thirty years.

Indian Health Resorts.

The Hill Stations of India are resorted to as an escape from the exhausting influence of the heat and the malaria so common on less elevated ground. Of these stations Sir Joseph Fayrer speaks as follows: "In the absence of organic lesions in important organs, such as liver, alimentary canal, lungs and heart, &c., the tendency to recurrence of the periodic forms of fever caused by malaria is lessened or prevented

by a sufficiently prolonged change to the hill sanitaria, whilst the whole system is remarkably reinvigorated. For such invalids and convalescents they are invaluable, though not quite equal to the more radical relaxation and change of climate involved by two long sea voyages with a more or less protracted sojourn in this country, or in some of the other salubrious localities of Europe. When, however, there has been developed any marked structural disease of the cerebral, thoracic, or abdominal organs, or even when, without any discovered or discoverable mischief of this nature to these parts, the blood, the digestive and nervous systems have become seriously impaired or damaged, experience has shown that removal to Europe is absolutely necessary to check the further downward progress and to secure convalescence. For such cases the hill climates are not suited. Moreover, it sometimes happens that invalids who have been weakened by heat and malarious fevers on the plains are liable to suffer from hill diarrhœa, especially at Simla, due probably to their previous enervated condition, diminution of air pressure, suppression of the action of the skin, bad water, and bad sanitation." Dr. Parkes believes it is because of the last two causes that such diarrhœa arises, and not simply because of the effect of the higher elevation, and specially because of unwholesome drinking-water. Among the stations named by Dr. Parkes are Darjeeling, Simla, Landour, Murree, Kussowlie, Nainee Tal, Dugshai, and Subathoo in the Bengal Presidency, the resorts of the Nilgherry range, Ootacamund, Wellington, Coonoor, Kotagiri in the Madras Presidency, and Mount Aboo, Mahableshwur, and Poorandhur in the Bombay Presidency. The first range from 4000 to 8000 feet above the sea-level, the second from 5000 to 7000 feet, and the third from 4000 to 4700 feet. If **Simla** be taken as an illustration, its lowest temperature is given by Parkes as 40° in the shade, and its highest as 80°, in June, with a total rainfall of 70 inches on an average. The fall is greatest in July and August, but from May to September the air is moist, and clouds and fogs are common. It is unsuited to the consumptive and to those with disease of heart or liver. Hill diarrhœa is common; and those liable to bowel complaint should seek some other station. It is believed to be free from malaria, and those weakened by such attacks, or in depressed health from overwork, &c., but otherwise sound, find it beneficial.

Murree, in the Punjaub, at an elevation of 7507 feet, has a temperature of 71° in June, the hottest month, and 36°·7 in January, the coldest, with an annual rainfall of 58·44 inches. It is well suited for Europeans who do not suffer from organic disease.

Landour and **Mussoorie**, in the North-west Provinces, the former over 8000 feet, and the latter nearly 7500, with a temperature of 70° to 74° in June, and 40° to 42° in January, the hottest and coldest months respectively, are also recommended as stations for those affected with malaria, and consequent disturbance of general health, but not where organic disease of heart, lungs, liver, or bowels exists.

Darjeeling, at an elevation of 6912 feet, situated in Sikkim, is said by Sir Joseph Fayrer to be, perhaps, the most salubrious of all the Himalayan sanitaria, and much of this is due to the comparative equability of its climate. Its highest mean temperature is in June, 63°·3, and its lowest in January, 39°·2; the rainfall is 118·24 annually. "Even very weakly children transported thither from the malarious plains soon become firm, plump, and rosy." In organic disease it is more beneficial than any of the other stations, though its chief benefits are derived by those suffering from functional disturbances only.

The **Nilgherry stations, Ootacamund** (7000 feet), **Coonoor** (6500 feet), **Wellington** (6200 feet), and **Kotagiri** (6500 feet) in the south-west of India, are called the Queen of Indian Sanitaria. Of them Fayrer says, "In the Nilgherries the invalid may exercise a choice of climate, not possible, in anything approaching an equal degree, at any of the other sanitaria brought under notice in this brief resumé. He may select Coonoor for its mildness, warmth, equability, and scenery, to prepare his constitution for the cooler and more bracing climate of Ootacamund; or, if his case indicate such necessity, he may remain there during his sojourn in the hills; or, to escape the south-west monsoon, its discomforts and disadvantages, he may find a pleasant and congenial refuge at Kotagiri, where its depressing influence is only experienced in a much mitigated degree. And when the north-east monsoon prevails at Kotagiri, from October to January, he may exchange residence there for Coonoor, where its force is only slightly experienced, or for Ootacamund, where it is not at all felt. The general experience of the many able physicians who have practised at these sanitaria tends to the conclusion that, whilst they are, at suitable seasons, particularly during the winter and hot months, eminently restorative

in cases of ill-health, caused by the heat and malaria of the low country, exhaustion of nerve energy, indigestion, portal plethora, and malarial fever, uncomplicated with visceral disease of a serious character, they are not advantageous to those afflicted with liver disorder, dysentery, phthisis, cardiac (heart) and brain disease. To those of all ages already in possession of sound physical and mental health, the Nilgherries, whether for temporary or permanent residence, stand out conspicuously as the most salubrious of all the known mountain climates of India. The children of European parentage, who remain all the year round, during the period set apart for educational training, are remarkably robust and healthy."

Mahableshwur, at an elevation of over 4500 feet, in the Western Ghats mountains, south of Bombay, is the summer residence of the Bombay government. Its season is from October to June. Between June and September is its rainy season, when the climate is hurtful to cases of rheumatism and of organic affections of lungs, bowel, liver, and heart.

Mount Aboo in Rajputana has an elevation of nearly 4000 feet. Its lowest mean temperature is 54°·2 in January, and its highest 77°·9 in May. June to September are its rainiest months.

We quote from Sir Joseph Fayrer, one of the highest authorities on the climate of India, the following practical rules: "Those who select India for a career should be in the enjoyment of fairly good physical and mental health. . . . The European should, if possible, make arrangements to arrive in India, at or near the commencement of the cold weather, or, at any rate, before its termination—say in November, and not later than January. The trying heat of the Red Sea, during the outward journey, is thus reduced to a minimum; and the transition from the autumn or early winter of this country to the genial cold season in India is found to be pleasant and healthful, whilst time is allowed, as the hot weather gradually approaches, for the partial accommodation of the constitution to the altered circumstances involved in the transfer from a temperate to a tropical climate. If, however, this is impracticable, the second best season for arrival, at some parts, under the influence of the south-west monsoon, is during July and August. But, in the event of this period being fixed upon for the voyage, the utmost care, in diet, drink, and clothing, must be taken to neutralize or mitigate the heat of Egypt and the Red Sea. Under such conditions, precautions must be had recourse to, to avoid anything like constipation, whilst the strictest abstinence from too highly seasoned food and alcoholic liquors must be enjoined. To time the arrival in India in April, May, and June—the hottest months—or during the latter half of September and most of October—the malarious season—is often to sow the seeds of cerebral (brain) and hepatic (liver) disease, which may give considerable future trouble, embitter subsequent residence, and foster an ineradicable dislike to the country. No one in delicate health, or who is not strong and vigorous, should be advised, or permitted to select these months for the commencement, or continuation of an Indian career."

"May and June, the hottest months, are not suited for leaving India, although some still do so, at the beginning of the former month, because it enables them to arrive in England in summer. But to the strongest, the voyage at this season is very trying—often to those in infirm health, fatal, especially in the Red Sea. . . . The danger is immensely increased by intemperance in eating or drinking. So it is in a journey across India, and thence to this country, in May or June. The climate of India during November, December, and January is so agreeable and salubrious that few who can remain leave it during these months." "February and March are the best months for embarkation, from any of the three principal Indian ports, especially for invalids, ladies, and children. The railways and inland river steamers now render it possible to reach these places, with expedition and punctuality, from the most remote districts. With sufficient forethought as to clothing and provisions, the longest railway journeys may be undertaken at this season in comfort and safety. . . . On starting from India, provision should be made for abundance of the warmest woollen and other clothing, to be utilized in the Mediterranean perhaps, the Atlantic and the Channel. Too much care cannot be exercised in thus securing the invalid, as well as those who are apparently in excellent health, against the evil effects of chill. Yet such a simple and self-evident precaution is too often neglected, and bronchitis, congestion of the liver, and recurrences of malarial fever are often the result, all of which might have been avoided. Those who are suffering from serious tropical diseases, or who have not recovered sufficiently from their effects, will do well to dally at any of the health resorts of the Mediterranean which

may have been recommended as suitable, and refrain from coming to England, until the month of June. Before this, the climate is usually unfavourable to recovery from chronic dysentery, malarial enlargement of liver, malarious cachexia, and tropical anæmia. Whereas, in conjunction with the appropriate treatment which can be commanded from English physicians practising at the southern sanitaria, sufferers are generally benefited by a stay there, until it is safe for them to proceed home. By the adoption of this course, the good effects of removal from the Indian climate and the sea voyage are maintained, and the chances of permanent restoration to health, after arrival in England, materially promoted."

Australian Health Resorts.

In these paragraphs we shall make some brief references to the climatic conditions in Australia, Tasmania, and New Zealand. Australia embraces a superficial area of 3,038,400 square miles, its greatest length from east to west being about 2500 miles, and from north to south about 1800. Moreover, one-third of it is in the torrid and the remainder in the south temperate zone. Tasmania, to the south of Australia, has an extreme length and breadth of 200 miles. New Zealand consists of two principal islands, about 1200 miles south-east of Australia, the united length of which, extending north-east to south-west, is 1163 miles, the mean breadth being 140 miles, and the total superficial area about 95,000 square miles.

We have put down these figures as explanatory of the fact that one cannot speak of the climate of Australia or New Zealand as if there were one prevailing kind of climate.

The seasons are: spring in September, October, and November, summer in December, January, and February, autumn in March, April, and May, winter in June, July, and August. The summer months are the months to be avoided, and the genial weather as a general rule begins about the last month of autumn and lasts till the middle of spring.

On the eastern side of Australia the northern portion is Queensland, the southern extremity is Victoria, and between the two is New South Wales. For purposes of convenience we have selected the chief towns of these divisions—Brisbane the chief town of Queensland, Sydney the chief town of New South Wales, and Melbourne the chief town of Victoria. The western side of Australia is called Western Australia, and we have taken Perth as illustrative of it. Between these eastern and western portions of Australia is a middle division, the southern part of which is South Australia, with its capital Adelaide. Hobart Town we have taken as representing Tasmania, Auckland as representing the northern island of New Zealand, and Christchurch and Dunedin as representing the southern island.

We have arranged these towns in a table, and have placed in columns the chief meteorological facts as to temperature, rainfall, &c., that we have been able to obtain.

	Queensland.	New South Wales.	Victoria.	South Australia.	Western Australia	Tasmania.	New Zealand (North).	New Zealand (South).	
	Brisbane.	Sydney.	Melbourne.	Adelaide.	Perth.	Hobart Tn.	Auckland.	Christchur.	Dunedin.

Brisbane is situated in the southern portion of Queensland. Its mean temperature is like that of Madeira. The winter season, from May to November, is the best of the year. Frosts are occasional, though not severe. The air is moderately moist, and the changes of temperature not so marked as farther south. The prevailing winds are from the south, cooling breezes in the southern hemisphere. Northwards from Brisbane the climate becomes more tropical in character. Westwards from Brisbane, inland that is to say, are several health resorts, situated at considerable elevations, and with a drier atmosphere in proportion to their distance from the coast. For example, **Dalby** (1123 feet above sea-level) is 152 miles west of Brisbane, in the district of the Northern Downs; **Harlaxton** (2003 feet) is 78 miles from the coast and

98 miles west of Brisbane. Its mean maximum summer temperature is said to be 82°, and in winter its temperature rarely falls below 32°. **Killarney** (1691 feet) is 73 miles from the coast and 194 south-west from Brisbane, and **Mount Perry or Tenningering** (2500 feet), 60 miles from the coast and 200 north-west of Brisbane, amid beautiful mountain scenery. All these resorts are recommended in lung affections, consumption, asthma, and such cases of bronchitis as need a moderately dry and bracing atmosphere. **Toowoomba** (1921 feet), 100 miles west of Brisbane, 80 miles from the coast, in the district known as the "Garden of Queensland," that of the Darling Downs, is recommended in convalescence from malarial fevers.

Sydney.—The winter season at Sydney is June, July, and August, and is generally very cold, mornings and evenings being chill and disagreeable. July is the coldest month, and the temperature may fall to nearly 42°. In the interior of New South Wales ice of slight thickness is occasionally met with. Dew is heavy and fogs are common on low-lying situations. The spring months are pleasant and clear. The heat of summer is moderated by the sea and land breezes, the period when the sea breeze dies down in the evening and before the land breeze begins being one of considerable oppression. The unpleasant feature of the summer is the occurrence of hot dry winds from the north-west, which occur, on an average, four times every summer, though they last not usually longer than twelve hours, during which time the thermometer may rise to 90°, 100°, and even higher. These winds suddenly change to a violent southerly wind, which is attended by a rapid fall of temperature and usually some rain. The temperature in one half-hour, while this change is in progress, may oscillate through a range of 20° or 30°. These rapid changes make the climate very trying to anyone with lung affection. The relative moisture of the atmosphere varies between 67·5 and 77·5 per cent of saturation, and is highest in autumn.

West from Sydney on the Blue Mountains are health resorts, suitable for the more trying months of summer. Such are **Bowenfels**, nearly 3000 feet above sea-level, 78 miles from the coast, and 97 west of Sydney, **Katoomba** (3349 feet), 66 miles west of Sydney and 58 from the coast, the summer temperature of which seldom exceeds 75°, **Lawson** (2399 feet), 58 miles west of Sydney. Beyond the Blue Mountains are **Bathurst** (2153 feet), 145 miles west of Sydney, with a mean annual temperature of 56°·8, and **Goulburn** (2071 feet), 134 miles south from Sydney, with a mean annual temperature of 55°.

Diseases of the lungs are common among those belonging to Sydney, chiefly among the young of both sexes. This, it is said, is due mainly to the sudden changes to which the temperature is subject, as already noted. Dysentery is also common. Infectious diseases of children are practically unknown. Sydney is, therefore, not recommended in advanced disease of the lungs. But the climate is so healthy and delightful, except in the three hot months when the north-west wind occurs, when, however, escape to higher regions is possible, that for those who, though not advanced in consumption, have yet a consumptive tendency, but who must find a residence in a town where employment is to be had, Sydney is one of the places to be named, though Tasmania is held in higher repute.

Melbourne, the capital of Victoria, was formerly held in repute as affording a suitable climate for consumptive patients. It is in winter colder than the localities already named; and it is liable to sudden and uncertain changes of temperature throughout the year. It is also subject to hot winds from the north and storms of dust, very injurious to any suffering from lung affections, and the deaths from consumption are now nearly as numerous as in large towns in England. December, January, and February are the hottest months, and July is the coldest. The hot winds of summer are followed by strong breezes from the southward, which cause a rapid fall in temperature, amounting to 20° or 30°. In autumn "cool winds, Italian skies, gentle rains (at night) and a bright clear atmosphere, impart a spirit of strength and activity to the inhabitants which is not surpassed by any country in the world." Mountain resorts are also within reach of Melbourne, principally to the north-east. **Beechworth** (1795 feet) is 171 miles north-east, with a temperature in December of 67° and in July of 40°, and is more suitable for chest affections than Melbourne itself. **Ballaarat** is 100 miles west, at an elevation of 1427 feet, and is a noted resort for invalids. Its December temperature is 60°, and its July temperature 42°, and its air is bracing and moderately dry. **Ballan**, 45 miles north-west, has mineral springs, used for digestive complaints and kidney affections. **Alexandra**, 90 miles north-east, is suited for lung and kidney disorders. It lies amid a mountainous country, at an elevation of 1000 feet. **Charlton**, 173 miles north-west, is much more equable,

free of the sudden changes of temperature of Melbourne, and more fitted for consumptive patients.

Adelaide, the capital of South Australia, is 7 miles from the sea, has a milder temperature and more equable climate than Melbourne, but is inferior to Sydney and Tasmania for consumptives. December, January, and February are the hottest months and July the coldest. But the air is dry, and though in midsummer the temperature stands sometimes at 100° in the shade, the dry air renders it more tolerable than it would be in a moist atmosphere. Between April and October is the pleasantest season. In summer the hot north winds blow "like the blast from a furnace," accompanied by fine dust in clouds. Lung affections are common, and diarrhœal diseases.

Perth is the chief town in West Australia, a portion of the island said to be the healthiest of the Australian colonies. The table on p. 806 indicates a higher mean temperature than that of any of the other towns named, with a very hot summer. Its hottest month is February and the coldest are July and August, in which months the greatest rainfall occurs. The best season is from October to April; and the hot winds, which plague Melbourne and Adelaide, are not here so frequent or so severe. Western Australia, according to Mr. Ferguson, the colonial surgeon, has a death-rate of 12 per 1000, against 15 per 1000 for New South Wales and Tasmania.

Hobart Town is in the south of Tasmania. Tasmania has, on account of its smallness, a more marked insular climate than Australia. It is much more equable. Even in the height of summer the evenings and nights are cool and refreshing, and in winter the cold is never very great, not more severe, it is said, than that of the south of France. December, January, and February are the summer months, and the three following autumn months are the most enjoyable of the year. "The sky is then clear and serene, the days moderately warm, and the evenings and nights mild and genial." The north-west wind, which occasionally blows in summer, does not last long, though its heat and dryness are still unpleasant. The equability of the temperature make Tasmania more desirable for those suffering from lung affections than any of the Australian towns, though the comparative moisture of the atmosphere renders it still inferior to the high mountain altitudes of Central Europe, or of North and South America, for consumptives. It is very suitable for those exhausted by hotter climates.

Auckland, in the north New Zealand island, exhibits in its temperature (see table on p. 806) the chief characteristics of the New Zealand climate, equability and geniality. It is temperate also, and somewhat moist, the northern island being warmer than the southern.

Christchurch and **Dunedin** show the lower temperature of the southern island, though their range of temperature is not greater than that of Auckland, and if colder they are also equable. On the west coast of both islands the climate is less changeable than on the east coast. The rainfall on the west coast of both is very much greater than that on the east. Thus while at Christchurch on the east it is 25½ inches, at Hokitika, nearly opposite on the west coast, it is 112 inches. North-west winds prevail in the winter months and south-east in summer, but the hot winds are absent. The winter is severe at Christchurch and Dunedin, but more temperate and mild at Auckland and New Plymouth on the west coast of the northern island.

The diseases prevalent in summer are diarrhœa and dysentery, and a number of deaths occur from consumption throughout the year; and there is said to be a tendency among the colonists to rheumatic troubles.

It appears, then, that no locality in Australia, Tasmania, or New Zealand, is suited for advanced cases of consumption; that where a desire existed to avert a threat of consumption, not actually developed, Tasmania, Sydney, or Western Australia might be chosen, if the higher altitudes of the Swiss Alps or the Colorado Mountains were not open to the person; and that these islands of the southern hemisphere offer bright and genial climates to all in good health, and a pleasant and beneficial resort to those suffering from the enervating effects of tropical heat such as that of India.

PART III.

MEDICINES AND THE PURPOSES FOR WHICH THEY ARE EMPLOYED.

INTRODUCTION.

The Rational Employment of Medicines:
The Meaning of Therapeutics, of Rational and Empirical Treatment.
Modes of Administering Medicines:
Administration of Medicines by the Mouth, and by Injection into the Bowel;
Hypodermic Injection—Injection under the Skin;
Administration by Rubbing on the Skin, by Inhalation, by Baths, &c.
The Dose of Medicines:
Table of Doses suited to Different Ages.

The Rational Employment of Medicines.

The "practice of medicine," that phrase being used to mean the business or work of the medical practitioner, is inseparably associated, in the public mind, with the prescribing of drugs. The man who suffers from some discomfort, some disorder or other, a pain in his stomach, a pain in his head, a bad taste in his mouth, a want of appetite for his usual food, a cough, sleeplessness, or other ailment, presents himself before his doctor. What he expects to follow is something like this. He will inform the doctor that he suffers from indigestion, or that he "wants something for a bad cough," or that he is troubled with headache, or whatever his complaint may be; thereupon the doctor may go through a few formalities, such as looking at his tongue, feeling his pulse, and so on; then he will write a prescription, which the patient takes to a druggist; the druggist prepares, as ordered, a mixture—"a bottle"—or a pill, or a powder, which when the patient has taken, his stomach-ache or headache, or cough, or sleeplessness, ought to depart. These are the lines of the orthodox routine, "without which none is genuine," according to the generally held public view of the doctor's duties. There are, of course, variations in detail. One patient will interrupt the doctor, when he is about to ask a few questions, with such a remark as, "Oh! I know quite well what is wrong; it is just indigestion; can you not give me something for it?" Another is not sufficiently impressed with his adviser's care and attention unless the adviser puts him figuratively into the witness-box, examines and cross-examines him, produces a big book and duly enters the answers to the questions, and writes up a long statement of "his case." In the end, however, whatever be the course chosen, the bottle, pill, or powder must be ordered. That this is the view prevailing, more or less, among all classes, among the learned as among those unlearned, is daily illustrated in the work of every practitioner of medicine. "What is good for a cough, doctor?" "I wish you would give me something to cure my headache," and so on, are among the everyday requests, addressed to the medical man. There is some drug or other which is suitable for the removal of every ailment, is the general belief which prevails. If one doctor does not hit on the appropriate remedy another may, and so one doctor is tried after another, which is to say, one drug is tried after another, or one combination of drugs after another. If the cure is not obtained it is because the appropriate remedy has not been ordered or has not yet been discovered. One sufferer from indigestion has had some remedy prescribed which has proved effectual, and he hands round the prescription among any of his friends who suffer from a like complaint, with the perfect assurance that it will relieve them as it relieved him. The progress of medicine will thus consist in the discovery of new drugs, or in the application of drugs already known in new ways or for diseases they have not hitherto been supposed to be useful in. Now this is altogether a very imperfect view of the medical art, and an exaggerated notion of the value of medicines. The man who asks what is good for a cough, and expects an answer as promptly as he would to the question, what will remove ink-stains from linen? or what will cure a smoky chimney? overlooks the fact that his body is a complicated organism, a combina-

tion of numerous associated organs, working for a common end, the sphere of action of a multitude of intricate processes, and cannot be handled as a lifeless thing, a part of which can be acted on without the whole being more or less affected. He overlooks the fact that the healthy action of his body is the result of a multitude of conditions, connected with the food he eats, the water he drinks, the air he breathes, the clothing he wears, the house he dwells in, the daily work he performs, and the circumstances of his social life, and that the unhealthy action of his body may be connected with any, or many, or all, of these conditions. The man who treats disease on rational principles does not seek simply to determine what is the proper name to attach to a complaint from which his patient suffers, in order to say what drug is suitable for it. He seeks rather to obtain a knowledge of the conditions under which his patient lives, of the manner in which the various organs of his body are performing their work, whether their performance is of a healthy kind; if not, wherein they are defective, or wherein they depart from the healthy standard. When he has determined these things to his satisfaction, he asks himself how this departure has arisen, what is keeping it up, what is encouraging it or preventing a restoration to the natural state of things. When the information thus obtained is before him, he probably has the means of deciding how the unhealthy action may be prevented, how a return to the healthy action may be promoted, what procedure is likely to encourage a restoration to health. It may be that to achieve this desired end drugs are not necessary, may, perhaps, be hurtful rather than the reverse. It is only too likely that the reason of the disturbance of the healthy activity of the body will be found in some of the conditions of the patient's life, in some error of eating or drinking, in some unhealthy state of the air of house or workshop, in some circumstance connected with the patient's trade or occupation. If the reason of the disturbance is found and removed, then the natural tendency of the body to conduct its operations in a particular way—the way for which it was designed, the healthy way—may be sufficient to restore health, and the cure is thus effected without drugs. It may be possible to quicken the process of restoration by administering some substance which is known to have some particular effect upon a certain organ of the body, by whose effect the disordered action may be lessened and the tendency to return to the natural action encouraged. In which case the medicine is ordered; but it is not the cure; it is only one of the helps to a cure. It is given only to reinforce the other means set in operation to effect a return to health.

The treatment of disease, then, is not solely, nor mainly, the administration of medicines. The administration of medicines is only one of the means of treating disease, one of many means, though undoubtedly, when wisely directed, a very valuable means. The tendency to return to natural healthy action—the *vis medicatrix naturæ*, the healing influence of nature—or, from another point of view, the natural resistance of the body to disease, is what the wise physician mainly relies on really to cure the disease. This influence he encourages, excites, stimulates; difficulties in its way he tries to modify or remove; he "stands by," to use a nautical phrase, to modify or avert any interference with its full play which he sees likely to arise, or finds actually existing. For this purpose he directs the kind of food and drink to be taken, the most suitable climate, and for this purpose he employs what medicine he deems advisable. So it is that the use of medicines is only one, and not the chief, means adopted in the treatment of disease. The word **therapeutics**, therefore, which is commonly used in a narrow sense to imply the use of drugs in the treatment of disease, has a far broader meaning. It is derived from the Greek *therapeuo*, I heal, or I treat, and it really includes every means employed to restore a healthy state to the body.

These considerations will help us to understand the kind of knowledge that is needful for the successful employment of medicines. The physician must first know what the healthy action of the body really is. He must learn what the healthy action of the heart, lungs, liver, bowels, nervous system, all the organs of the body, is. He must be able to appreciate what changes are produced in those healthy activities by various states of disease; he must be able to search for, and detect, a departure from the natural state, and understand its nature and its effects. He is not yet ready, however, to treat disease. It is not enough to know how the body works, so to speak, when it is in health, nor yet sufficient when, to that knowledge, is added an ability to discover when it is working badly and why. For he does not yet know how its healthy action is affected by various conditions, nor how he can bring influences to bear on its disordered action. To the knowledge of how the body works when in health, must be added an understanding of the various means

by which that healthy action can be influenced. For example, a man may know a great deal about the action of the heart, how often it contracts during one minute, with what force it contracts, what the order of its movements is, what are their effects, and so on, and yet be unable to tell how the action of the heart may be quickened or slowed, weakened or strengthened. Or again, one may know a good deal about the liver, what is the build, size, shape, position of the organ, about its work in the body, about the bile which it produces, what its chemical and other properties are, and so on, and yet have not the smallest knowledge of any means by which the liver may be stimulated to increased action, to produce more bile, or how its action may be diminished so that it produces less, and so on. If one is not aware how the various activities of the body may be influenced by conditions either within or without the body in a state of health, how can one understand how to influence the action of the various organs when there is some state of disease? If one cannot tell how the action of the healthy heart may be strengthened, how is one to know what to do to strengthen a heart so weakened by disease, as to have become almost unfit for its work? If one is not aware what will slow the movements of the healthily beating heart, how is one to know what to do to diminish the speed of action of a heart beating with a rapidity which threatens rapid exhaustion of all power to beat at all? If one is not aware how to stimulate the flow of bile from the liver in a state of health, how is one to know what to do to "poke up" a liver which has become slow in the performance of its share in the work of the body. The training of the physician, then, implies the opportunity of becoming acquainted with the effects upon the body, and upon its various organs when in a state of health, of various conditions and substances, and an acquaintance, so far as that can be gained, with the effects of similar conditions and substances on the manifold disordered states to which the body is subject. The knowledge of the influences that may be brought to bear upon the *healthy* body it is the business of the science of physiology to acquire, and the effect of any substance upon the body in a state of health is said to be its physiological action. The study of the effects upon the body in a state of disease belongs to the science of therapeutics, the science of treatment.
